That cancer is most frequent about the time of the menopause has been observed by every writer from Hippocrates to the present day. Hippocrates believed that it was due to the suppression of the menses, and tried to reëstablish that function. Hunter observed that the cancerous age was from forty to sixty in both sexes, though it might occur sooner or later; but that when cancer of the breast occurred in a woman under forty its course was more rapid and more extensive than in an older woman; so that operations succeeded better in the latter on this account. He believed that it was the changes incident to the menopause that rendered women more susceptible at that time.

From the time of Paré, it has been observed that cancer is more frequent in women than in men; and that the parts most disposed to cancer are the breasts and uterus.

Parsons (1835) said that the persons most subject to cancer are antiquated maids, next those mothers who have not suckled their children, and least those who have borne children and have suckled them with their own milk. Williams (1898) said that cancer of the breast was almost as frequent in the unmarried and sterile as in those who have had children. While uterine cancer is of more frequent occurrence in the married, and in those who have borne children than in the single and sterile. Subjects who have cancer of the corpus uteri are much less prolific than those with cervical cancer.

The belief in an hereditary predisposition to cancer is older than Hunter. Johnson (1808) said that predisposition to cancer might be hereditary or acquired. That from the frequent occurrence of cancerous affections in different individuals in the same family, especially in the female line, might be deduced one strong argument of their hereditary nature. Parsons (1835) said that the cancerous diathesis is often hereditary is now generally so well understood, that eminent surgeons advise families in which a case of cancer of the breast occurs, to guard the general health of the females at the time of the cancerous age. Cohnheim said that the inheritance had just as often been observed to occur through the paternal as through the maternal side. Paget found carcinoma of the uterus in three generations, mother, grandmother, and daughter. He collected the history of 322 cases with especial reference to this point; of this number there were seventy-eight, or nearly one-fourth who were aware of cancer in other members of their families. Senn says that it is evident that when a tumor is inherited the two essential causes are transmitted from mother to child; first, a matrix of embryonic cells, and second, a lack of resistance on the part of the whole organism, or of the tissues in the immediate vicinity of the matrix, to retard tissue growth.

Parsons believed that the foundation of the disease was laid in a cancerous diathesis, that might evolve cancer spontaneously, though it was often preceded by some slight irritation or injury of the part. But that it was not probable that any such local irritation could assume a cancerous character, where the constitutional diathesis did not exist; yet that it might serve as a nidus, in which the disease would appear sooner than it would have spontaneously, and that it was not impossible that such a diathesis might exist throughout life, but from the absence of such local irritation, or because the diathesis was feeble, it might not be evolved. Rokitanski held that carcinomata were more often associated with a dyscrasia than not, which, he said, in point of fact, often preceded and engendered the cancer.

Climate as an etiological factor in disposing to and preventing cancer has been noted by writers from the time of Hunter to the present. The almost entire absence of cancer in the tropics has always attracted attention. In speaking of this fact, Hunter said, that in the Friendly Islands the women fought for prizes and aimed chiefly at the breast. Johnson considers the disease more frequent and intractable in the cold, northerly regions, than in the temperate zones, while he said that in the southern parts of Europe, it was seldom attended with any considerable danger to life. Dalgetty (1902) said that, in working at Adampore in South Sylhet, he had to deal with an imported laboring class of 12,000 Hindus of all ages, and of a resident population of 15,000 Mussulmen; and that during five years' experience he had only met with eight cases of malignant disease. But he thinks that it is improbable that there is any antagonism between malaria and cancer; as he believes that every case in the above list had suffered from malaria. He adds that the Eastern races do not live to the age at which cancer is most common in Great Britain, but that age is only a relative term, and that a native of India might be an old man at thirty.

Savages are believed to be almost or quite exempt from cancer. It has generally been believed that the laboring class furnished the largest contingent to the whole number of patients suffering from carcinoma; but these statistics were almost exclusively gathered from the records of hospital physicians. A more careful inquiry shows that the reverse comes nearer the truth. M. d'Epine found, in examining the mortality statistics of malignant tumors of the city of Geneva, that among the

well-to-do classes there was from this cause 106 deaths to every 1,000 inhabitants; while the poor only furnished 72 to 1,000. Walsh found that of a million of people of London in ten of the unhealthiest districts, 127 died of malignant tumors; in ten healthier districts 183; and that in ten of the healthiest, 199. From similar statistics gathered in England and Wales, Moore came to the conclusion that cancer became more frequent with the increasing prosperity of the people. In the United States cancer has been on the increase with the progress of of civilization. The mortality was from this cause in 1850, 9 to every 100,000 inhabitants; in 1860 it was 11.79; in 1870, 16; in 1880, 26; in 1890, 33.5.

In the middle of the seventeenth century Zæntus Lusitanus stated his belief that cancer was contagious and cited cases. In 1672 Nicolaus Tulpius, the famous anatomist, was so sure of it, that he stated that an ulcerated cancer was just as contagious as inflammation of the eyes. Juncker (1731) said that successful engrafting necessitated that the infective material should fall on a suitable place where there was already a breach of continuity. In 1773 the Academy of Medicine at Lyons discussed the subject. Cancer was regarded by Hunter as the result of a morbid poison, which either arose spontaneously or was derived from the contagion of similar diseases; he compared cancer to smallpox, syphilis, and tubercle. Carmichael hints at the possibility of the parasitic origin of cancer, it was supposed to originate spontaneously. Johnson gave the experiments which Mr. Nooth made on himself repeatedly during the year 1777, with negative results. Aldis, 1832, said that on the theory that most of the diseases were conveyed into the system through drinking water, it was recommended that only distilled water should be used.

All writers of the present day are agreed that every tumor is benign in its origin; that cancer always begins as a local disease; that once generated, it spreads by infecting its immediate environment; that it is disseminated metastatically by the blood current and the lymph streams, the latter infecting the glands *en route*; the disease becomes constitutional and the well-known cachexia is gradually established by the victim becoming saturated by the toxin of the disease. Another well-known fact to surgeons is the infection of the wound during operations for the removal of cancerous growths. Bland-Sutton says, "In removing the infected organ, the infected lymphatics and blood-vessels stuffed with cancerous material are divided and the cancer cells let loose over the tissues, which they infect, and lead to an extensive outbreak of local cancer."

Still another argument in favor of the theory that cancer is caused by microparasites is the fact that cancer has a selective affinity for epithelial surfaces and particularly for mucous membranes. And those glands that are in most direct communication with the air or intestinal gases are most prone to become infected with cancer—for example, the mamma, rectum, and stomach. From the large percentage of occurrences in the alimentary canal it has been believed that the infective agent might be ingested. The other favorite sites are the organs of reproduction of the species and those for the nutrition of the young. Supposing the infecting microbe to be a habitat in the soil, it has been suggested that the dress of women would favor the frequency with which cancer of the uterus occurs.

Wherever cancer grows luxuriantly and rapidly we find present the chief desiderata for the growth of bacteria, namely, moisture, a suitable nutrient medium, a constant temperature favorable to the growth of bacteria, and the exclusion to light and air. The great frequency of cancer in the cervical endometrium in comparison with its infrequency in the corporeal endometrium, and its extreme rarity in the mucous membrane of the Fallopian tube are facts which favor the parasitic theory of cancer.

The infectiousness of cancer does not seem to be very great. The normal physiological resistance of the tissues is sufficient so long as there is no breach of continuity of structure. When, however, this occurs from prolonged irritation, and especially if at the same time the general health is impaired, vulnerability is induced. In all probability cancer does not arise in sound, healthy tissues. The uterine cervix is rendered vulnerable in the parous woman by lacerations, in the parous, nulliparous, and unmarried woman the cervix is frequently eroded by acrid discharges.

Inflammation is never the sole cause of tumor formation, but it always hastens it, this is especially true of malignant tumors. If a tumor matrix is within the limits of an inflamed area, it suddenly receives an increased blood supply, which alone may be sufficient to arouse it from its dormant condition into active proliferation, at the same time that the inflammation lessens the physiological resistance. The more rapid development of cancer in pregnancy is due to the size of the lymph spaces, and in child-bed is due to the activity of the circulation. In senile women the vessels are narrow and the lymph activity is trifling, consequently the extension of the disease is very slow.

The number of cases of auto-inoculation is very considerable. Ebert collected twenty-three cases of contact cancer, such as lip to lip, tongue to gum, one labium majus to the other, and so forth. He also mentions the case of a woman who inoculated the corner of her eye from a cancer on the back of her hand.

Behla gives a number of instances of cancer *à deux*, quoting the names of the observers. Thus Boas mentions the case of a daughter who inoculated herself with rectal cancer by using the same enema syringe her mother had used during her fatal illness which was of the same nature. Tross reports the case of a man who developed a carcinoma of the glans penis, presenting a structure identical to the cervical carcinoma from which his wife suffered. Thirty other cases of a similar nature were reported. Guelliot has also collected twenty-eight such cases. Brand cites a case from his own practice in which a woman with cancer of the breast was nursed assiduously by an apparently healthy woman of forty-five years of age. This last-named woman died of cancer of the stomach within twelve months of the woman she had nursed. She was in constant attendance, and not being a particularly cleanly person, it is probable she had eaten her food with hands unwashen after dressing an ulcerated sore or handling the dressings. Some accidental inoculations in connection with operations have been reported.

Parks says that the failure to inoculate animals with cancer cultures is no evidence against this theory, we do not know that this can be done in animals by the forms which produce it in man. We know that syphilis and various other diseases are not communicable to animals.

Cancer seems to be chiefly a disease of the temperate zone, and in certain belts of this zone it is most prevalent. The highest death rate from cancer is in districts which lie low and are liable to occasional floodings and characterized by alluvial soil and sub-soil of various clays. On the other hand, cancer is least prevalent in elevated districts where there is a good fall of drainage, freed from floods and

characterized by porous sub-soil, especially the limestone. It is most rampant where the sewage is most difficult to be got rid of, and where it is most likely to be deposited and remain after floodings or high tides on a non-porous sub-soil. This permits and fosters the growth of the microorganisms, and the frequent occurrence of shallow surface wells in such districts suggests an easy and extensive contamination of drinking water. "Cancer houses," and "cancer rooms" in these houses, are reported. In the rural districts of Normandy cancer was found to be three times as prevalent as in Paris. Mason says that the consecutive houses in the same street are often found to be cancer houses, due to their having the same faulty system of drainage. Many such houses have beneath them disused cesspools or decayed brick sewers. A large percentage, 17 per cent., are end houses of rows, or corner houses of streets, where any defect in a drain would be most likely to be severely affected by sewerage. The older houses are more likely to become cancerous than the more modern ones, the drainage system being less perfect.

While the etiology of cancer has occupied the attention of the most eminent men in the medical profession for centuries, the interest in this study has recently been renewed by the bacteriological researches made to prove the microbic origin of this disease. This at least furnishes the best working hypothesis for the discovery of the cure of cancer.

Treatment.—To review the subject of the medical treatment of cancer would be to name almost every drug that has been known from the earliest antiquity to those of the present day. With every new discovery has arisen the hope that here, at last, had been found the specific for the cure of cancer. So it was on Priestly's discovery of carbonic acid gas, and so it was on the latest discovery of radium.

Caustics and escharotics have been used from the earliest times. Surgeons have constantly increased the field of their operations, hoping that by operating in healthy tissue and dissecting out lymphatics, thus wholly to eradicate the disease, and so cure the patient. How futile this has been, the large percentage of recurrences prove.

Electricity has been used in all its forms. The forms now in use are the *x*-rays and the violet rays. By this means it is hoped so powerfully to affect the molecular changes that go on within the cells as to act as a tonic and restorative to the protoplasm itself, to the end that metabolism may be promoted, and the resistance to adverse influences augmented. The immediate effect of this would be to restore the lost equilibrium.

The antitoxin treatment has only been tried to a very limited extent. And just here is the place that the best results must be looked for. Loeffler (1901) quotes Professor Trnka's work, Vienna, 1775, which directs our attention to a new method of treatment for carcinoma, so that we can use malaria as a therapeutic agent. As Gerhardt first, and after him many Italian observers, proved, malaria can be introduced into the system through the injections of the blood of an individual suffering from that disease under the skin, or directly into the blood-vessels of healthy individuals. Through the latest investigations it is known that we can, through the sting of a mosquito that has drawn the parasite of malaria into its body, produce malaria at will, and we can by the aid of quinine control the malaria. It has been noted by various observers that the infective diseases retard the progress of carcinoma. Loeffler strongly urges the experimental use of malarial inoculations for the cure of carcinoma as not only permissible but advisable.

Résumé.—Some of the more striking features of this review of the study of cancer covering the last two hundred years are that (1) cancer is almost totally absent in the tropics; (2) cancer is very rare among savage races; (3) with the advance of civilization, and the increased prosperity of the nations, there has been a steady and marked increase of cancer; (4) this disease is more prevalent among the well-to-do and wealthy than it is among the very poor; (5) it is more common among women than among men; (6) it is a disease par excellence of the climacteric; (7) it is hereditary; and (8) in order for tumors to become malignant a lessened physiological resistance of the local tissues, or of the body in general is necessary.

With our present ignorance of the cause and cure of cancer the first step taken must be in the direction of prophylaxis; when a woman reaches the age of forty she must be placed in the best possible condition for the resistance of this disease, by local treatment, in case there should be any local inflammation, lacerations, or ulcerations; and, secondly, her general health must be looked after, especially as regards diet, exercise, and life in the open air. Should cancer make its appearance, an immediate operation is imperative. If the case when first seen is too far advanced to make operation advisable, or should there be a recurrence of the disease, the *x*-rays and violet rays, combined with serum therapy, offer the greatest hope—at present we can only say of the alleviation of the disease and its sufferings. Based on the absence of cancer in the tropics, and that other well-known fact "that light is capable of killing the tubercle bacillus," to the above treatment should be added that of direct sunlight, which could be secured by adding solariums to our hospitals.

In view of the facts of the great and increasing prevalence of cancer, and the inadequacy of the present surgical resources to cope with it, it is to the renewed clinical study of this disease, which has almost been lost sight of, and to experimental serum therapy that our attention must now be directed to seek the cure for this most terrible and fatal of the diseases of the present day.

ELECTRICITY IN MEDICINE.*

By A. D. ROCKWELL, A.M., M.D.,
NEW YORK.

NEUROLOGIST AND ELECTRO-THERAPEUTIST TO THE FLUSHING HOSPITAL; FORMERLY PROFESSOR, NEW YORK POST-GRADUATE MEDICAL SCHOOL; EX-ELECTRO-THERAPEUTIST WOMAN'S HOSPITAL IN THE STATE OF NEW YORK, ETC.

In assuming the duties to which you have called me, it seems fitting to say to the members of this association, and especially to those who have but recently become interested in this fascinating field of research, that widely different conditions confront them than confronted those who did the pioneer work of electrotherapeutics.

Then there existed but the rudest constructions for practical work and no instruments of precision. Now we have at our command innumerable gradations and manifestations of electric force, and while yet we know not what electricity is we so understand the laws which govern it that it becomes obedient to our will in innumerable ways. Here, as a part of this wondrous exhibition, we are literally "in the midst of a boundless arsenal filled with all the weapons and engines that man's ingenuity and skill have been able to devise," and we impatiently await the originating genius who shall give to us some fundamental principle that will lift the subject of electricity in medicine to a far higher plane of scientific exactness and efficiency than it has yet attained. I firmly believe that we have in this all-pervading force something that has an inherent potency and promise of development that will render it more nearly a panacea than any other one thing. As yet no approach to any such claim can be made for it. In many ways empiricism still attends its use, and it is still the home of much of ignorance and credulity. But deep within the soul of man lies a "creative spirit which can fashion everything that is destined to exist," and which will some day arouse the world to its vast powers and possibilities in medicine. What part shall we have in this renaissance, in this phenomenal development which is sure to come? What nationalities and what individuals will be foremost in rearing the indestructible structure of an advanced therapeutics? American genius and enterprise, it seems to me, hold a place, all their own, among the peoples of the world, and the derivation of one of our striking characteristics is illustrated in the story regarding the elephant. If a Frenchman, a German, and an Englishman were each asked to write a full description of the elephant—his size, physical structure, habits—in short, the characteristics which differentiate him—their several methods of procedure would be as follows: The Frenchman would gaily repair to the *Jardin des Plantes*, note what he could see of the animal in his environment of captivity and immediately proceed to write his description. The German would repair to his study and, from the depths of his moral consciousness, evolve his idea of the nature of the animal; while the Englishman would immediately fit out a vessel, provision it for a six months' or a year's trip, seek the animal in his native haunts and write his description from an actual practical knowledge. The Englishman is the practical man, and from him the American inherits his genius for practical application.

What we lack, however, in the department of intellectual effort is the attribute of creative power. The man with imagination who is content to wait patiently and draw little by little from the depths of his moral consciousness is the man who evolves ideas that are concerned with principles that are eternal. The kind of thing that he does comes to the world as practically a creation. The American mind is fertile in invention rather than in original conception. The thing created by the more profound and subtle thought of originating genius is taken in hand by inventive genius and put to a score of practical uses. It ingeniously juggles with something the world already has in its possession, and the results are of undoubted value and of wide application, but it does not, like the creative faculty, reveal some hitherto unknown universal law whose discovery constitutes an epoch in the world's history. What it does is more for the day and hour, useful in its time and place, but soon to be superseded by other and higher forms of construction.

The discovery of gravitation, of the power of steam, the discovery of Galvani that gave us the galvanic current, and of Faraday showing that magnetic influence can induce currents in neighboring circuits are veritable creations that have revolutionized life. And so, too, with those recent epoch-making discoveries, along the line of, or kindred to, electric manifestations, the *x*-ray and radium. The discovery of radium was no mere accident, but was the result of patient inductive reasoning, on the basis of the long recognized phenomenon of radioactivity in connection with some form of matter, and is likely to result in a radical reorganization of scientific hypotheses. We are wrong, therefore, when we say that in the realm of science Americans are noted for their originality. The haste which characterizes us as a people. The restless activity which demands at once the thing desired. The development of the perceptive faculties to the detriment of the imagination—all these tend to render the acutely intelligent mind of the American of to-day impatient of delay and averse to prolonged abstract thought. How rare the deep devotion to science and to pure truth!

* Inaugural address delivered at the annual meeting of the American Electrotherapeutic Association, held in St. Louis, September 12 to 17.

How rare the sublime resignation of the immortal Keppler! "Is it much for me," said he in his isolation and extreme need, "that men should accept my discovery? If the Almighty waited six thousand years for one to see what he had made, I may surely wait two hundred for one to understand what I have seen." All this and more is implied in love of wisdom, in genuine seeking of truth, the noblest function that can be appointed for man, but requiring also the noblest man to fulfil it. With mankind in general, however, and especially with our people and this generation, what will most quickly supply the need of the hour is the thing sought, and is pursued with such persistency of effort and with such alert activity that we are called the most inventive of people. Fulton gave us the steamboat, Morse the telegraph, Edison the electric light. In the popular mind these names stand to-day as the highest expression perhaps of original scientific thought. But high as these names stand, and justly as they are honored, they do not represent the highest grade of creative intelligence.

They were great inventors and magnificently solved the need of the time, but the principles with which they worked and out of which they fashioned the details of practical service were not of their creation. Watt is greater than Fulton, Galvani than Morse, Faraday than Edison. Every decade, each year even, witnesses the birth of innumerable inventions, many of which genuinely add to the comfort and progress of the race; but an intellectual creation, the discovery of a principle hitherto absolutely unknown, having in it the promise and potency of innumerable inventions, are so infrequent as to constitute veritable epochs in the world's history. This association is in its way unique. For more than a decade now we have met annually to discuss the relation of electricity to disease.

All other societies, whether of general medicine or some one of its special departments, have to do with many remedies. Herein lies both our strength and our weakness. Our strength, because in focusing our energies and keenest intelligence upon a single point, as it were, it may be possible to as truly illuminate it as does the concentration of the sun rays upon any given point. Our weakness, because in thus concentrating and limiting our efforts we may possibly come to forget that we are physicians first and electrotherapeutists after. The history of therapeutics is a history of blasted hopes. Where one new therapeutic agent has accomplished even a respectable fraction of what was in the beginning claimed for it, a hundred, perhaps, have miserably failed. It is human nature to aspire eagerly to be the first, or among the first, to exploit the new.

In the rush for precedence conservatism is cast to the winds and, instead of waiting for a wider experience before giving expression as to the advantages and limitations of the new agent or method, we too often rush into print with the grossest exaggerations, with statements of therapeutic result that will not for a moment stand the test of a closer analysis. Honesty of purpose and absolute integrity in clinical reports constitute the one great shield and buckler of defence against the false and shallow optimism of the charlatan. Yet it is not enough that we be simply honest. Charlatans, it is true, are not generally honest, yet charlatanism is not inconsistent with personal integrity. The man from whom the writer first obtained his impulse for investigation along these lines was unconsciously a charlatan. His experience was vast; his integrity beyond question; but the basis of his charlatanism was his profound scientific ignorance. He never enunciated an idea, neither did he understand the principles underlying the cures that were wrought. He worked blindly, and honestly believed that his simple, old-fashioned induction coil was equal to all sorts of impossible things, and well illustrated in his life and character the old truth that "the human mind follows the line of least resistance, believes what is easy and for personal interests to believe, and, except after the most careful training, cannot be trusted either to observe or to report its observations with accuracy." Combine, however, honesty of purpose with education and trained powers of observation and we have a lever which is capable of lifting this department of medicine to a plane of unquestioned honor and dignity.

For, say what you will, electrotherapeutics is even yet a *terra incognita* to the vast majority of practitioners of medicine, and is looked upon by many, if not with contempt, with polite and patronizing indifference. Let me urge, therefore, upon the members of this association, that while they abate not one whit their enthusiasm, to see to it that the judicial faculty be not subordinated to impulse and desire. "Be true if you would be believed." Understate rather than overstate, for in so doing the foundations we are now laying will become so strong, each stone in its structure so firmly mortised, that the superstructure will be an enduring monument to our honest and earnest endeavor. Finally, allow me to express an opinion and utter a word of warning. Many years ago a physician said to me, "Why do you not enlarge your peripheries?" If that remark was applicable to one who studied electricity as a whole in its relation to disease, how much more is it to him who studies but a part! To my mind a grave error has been committed by leaders in this special line of work in relegating practically to the "limbo of forgotten things" the electric modalities of Galvani and Faraday. Following their lead, others less distinguished have either abandoned or never attempted the use of those indispensable manifestations of electric force, the galvanic and faradic currents. Elaborate electric paraphernalia, static and high frequency, adorn the consulting rooms of many a physician who is quite ignorant of the fundamental principles on which is based the use of electricity in medicine, and who would be altogether perplexed if asked to differentiate in the use of electric modalities. Valuable as these newer forms of electricity are, they constitute not the whole of electrotherapeutics, and he who fails to study the art of differentiation, and confines his efforts to any one electric modality in response to the popular trend and because of ease of administration, will oftentimes widely miss the mark.

If in this brief presentation I have given expression to views that seem to you too pessimistic and have seemed to speak against a too lively enthusiasm, you will please attribute it to a temperament by nature conservative. In dietetics it is far from necessary for the most perfect health constantly to urge the taking of more food. The natural tendency of the healthy man is to overfeeding rather than underfeeding, which results too often in paralysis and decay. And so, too, in the therapeutic exploitation of new fields. Let once the commercial spirit overmaster the spirit of truth, as night follows day, so surely will our quest degrade rather than elevate the special department to the advancement of which our energies are pledged.

The Sydenham, Madison Avenue and Fifty-eighth Street.

Lichen Planus.—On the theory that from the lack of perspiration the surface of the skin is deprived of a natural acidity, lotions, ointments, and pastes containing boric acid have been tried with very gratifying results.—Eddowes.

THE IDEA OF GROSS CLEANLINESS IN SURGERY, AND ITS HARMFUL RESULTS.*

By ROBERT T. MORRIS,
NEW YORK.

Modern surgeons are apt to smile at the term "laudable pus," and yet the earlier surgeons were not so far wrong in their nomenclature after all. Along with the teaching of scientific cleanliness in the schools at present, there is developed the idea that wound discharges in general are unclean, and are to be removed. It is an idea of gross cleanliness that would appeal to one's kitchen maid, if he had the fortune to possess such a maid, and the application of the idea is full of harmful consequences. Trained nurses and the assistants on the hospital staff are so imbued with the idea of keeping wounds clean that it is difficult to teach them the advantages of skilful neglect. Let us consider in detail three classes of cases: Those in which we are to have epithelial repair, those undergoing connective-tissue repair, and cases in which we are to have endothelial repair.

A case representative of the first class would be one of an open incised wound of the arm, with granulation well under way. New hyaline epithelium is shooting out from the epithelial borders rapidly on all sides, but the new cells are so delicate that their area is barely visible to the naked eye. The surface of the wound is bathed in pus. If this pus is wiped away whole rows of young epithelial cells are disarranged, repair is delayed, and nature has to help out with an undue amount of connective tissue, resulting in a larger and harder scar. If the pus is washed away with an antiseptic, the corrosive action of the antiseptic damages the new epithelium. Even if the pus is removed by simply pouring on sterilized water, damage results. This is because water is corrosive, the chief reason for this being that it quickly absorbs salts by exosmosis from the new cells. A ready demonstration of the corrosive action of ordinary water is furnished by putting a couple of drops upon the conjunctiva. The conjunctiva smarts and becomes red, and there is a profuse lacrymal secretion, and several minutes elapsing before the irritation ceases. If we use a physiological salt solution there is no irritation, and new cells would be damaged only by the application of the solution with sufficient force to produce mechanical injury. It may be well to remember, by the way, that the six-tenths of one per cent. salt solution that is in common use is isotonic for frog's blood, but that the nine-tenths of one per cent. solution is isotonic for man.

If we place cotton or gauze ever so gently upon a surface undergoing epithelial repair, the dressing is harmful because new cells are caught in the mesh and torn away when the dressing is changed. A wound undergoing epithelial repair then, is to be carefully protected against cleaning, and it must have some protecting medium like silver foil, Cargile membrane, or Lister's silk between the new cells and the absorbent dressing. There is no objection, to be sure, against keeping the skin in the vicinity of the wound as neat as one pleases.

A case representative of the second class, one undergoing connective-tissue repair, would be furnished by a fecal fistula. Repair is conducted by the heaping up of new connective tissue cells in delicate granulation tissue, and gradual contraction of the wall of the sinus. If we think that the fistula must be kept clean in accordance with the idea of obtaining gross cleanliness, the water that is used may distend the contracting wall. If it is plain sterilized water, or water containing antiseptics, it will corrode the delicate granulations and delay repair. Such a fistula which would close spontaneously in a few weeks, can be kept open for months by conscientious and well-meant attention on the part of physicians and nurses.

Of the third class of cases, in which we are dealing with endothelial repair, an example would be furnished by a case of perforative appendicitis with extensive peritoneal infection; and these cases furnish a pretty large death rate in response to the application of the idea of obtaining gross cleanliness. An active warfare is in progress between the bacteria and the leucocytes. The bacteria are winning. If we open the abdomen quickly, remove the appendix, and do not stop to make too careful cleansing of the peritoneum, the patient retains his natural resistance, the tide of battle is turned, and the endothelium of the peritoneum attends to final cleansing, and to repair of its own defects. If we believe, however, that it is necessary to get the peritoneum as visibly clean as possible by washing and wiping, and by putting in gauze masses for drainage, the patient is deprived of much of his natural resistance by the severity of the surgery, and he cannot quickly manufacture leucocytes and carry on excretion and repair. It is very easy indeed to produce death in such an appendicitis case by conscientious attention, and I believe that more than one of my earlier patients was lost in this way.

It is more or less harmful to one's reputation to avoid giving way to the idea of gross cleanliness, and to employ skilful neglect instead, for such treatment is not generally approved by the nurses or the members of the family, or by many physicians. But the results are so quickly in evidence that one is likely to be impressed by the fact that previously he has been trying all along to do too much.

TRAUMATIC APOPLEXY.

By PEARCE BAILEY, M.D.,
NEW YORK.

It is the purpose of this paper to call attention to certain post-traumatic apoplexies which are essentially different from the hemorrhages in the membranes, or in the brain substance which are the immediate and direct results of laceration. For the occurrence of spontaneous apoplexy, pre-existing vascular disease is essential. A mere increase in blood pressure does not cause normal arteries to rupture. When apoplexy occurs, therefore, degeneration in the cerebral arteries is assumed. In how far injuries contribute to such degeneration is a vexed question, and one difficult to decide. The general causes of such degeneration, which is of slow course, are subtle and manifold. Advancing age, all chronic diseases, syphilis, some general infections (typhoid fever), and many poisons (lead, alcohol, and tobacco) contribute to this end. Psychic causes, such as grief, worry, excitement, are also important. With all these factors to be considered, it is well-nigh impossible to determine what place, if any, should be assigned to traumatic causes acting years before. Yet trauma to the head is frequently advanced as a cause. It has also been maintained (Bernhardt & Kronthal, *Neurologisches Zentralblatt*, No. 4, 1890) that general injuries which at first give the symptoms of traumatic neurasthenia result in progressive cerebral endarteritis.

After many accidents, factors in arterial degeneration are called into play, for which the accident is only indirectly responsible. For, apart from the physical effects on the nervous system.

the patient is liable to become the victim of various psychic symptoms, to which such accidents often lead. In addition, and this is especially true in the laboring classes, the patient is apt to be idle. As always, idleness means less exercise, less fresh air, less concentrated effort, and more alcohol, and more tobacco—all factors in the production of arteriosclerosis. Consequently trauma, if a cause of chronic arteriosclerosis, acts in more ways than one.

But there are three varieties of vascular disturbance occurring after injuries to the head in which the connection between cause and effect is close and indisputable. These are (1) apoplexy, occurring simultaneously with the injury; (2) apoplexy occurring shortly after the injury; (3) apoplectiform symptoms occurring a long time after the injury.

1. *Apoplexy occurring simultaneously with the injury.*—In these cases, rare, but of great medico-legal importance, the patient, immediately after a blow on the head, develops the symptoms of a hemorrhage of the internal parts of the brain. Usually the blow is not severe, and all evidences of injury to the scalp or skull may be wanting. The symptoms are those of spotaneous apoplexy, and may be quickly fatal. Or there may be hemiplegia involving arm, leg, and face, with more or less recovery. Such hemiplegia is more complete than in traumatic cases, and the evidences of irritation, and the symptoms of concussion are wanting. In addition, unmistakable signs of general vascular degeneration are present. In a recent case the patient was struck on the head in a street brawl. He became momentarily unconscious, and completely hemiplegic. Examination, a few days later, showed left hemiplegia, complete restoration of psychic function, no general brain symptoms, but a well-marked arteriosclerosis of the peripheral arteries, and an hypertrophied heart with a systolic murmur at the apex.

The explanation of these cases consists in a pre-existing weakness, by miliary aneurysms or otherwise, of the walls of the cerebral arteries, which, when subjected to a sudden rise in blood pressure, give way. It is possible that the rise in blood pressure is due to the mechanical effect of the blow. But in many cases attendant circumstances leave little doubt that the psychic factors of fright and excitement were the most active causes in the blood pressure increase of the consequent extravasation.

2. *Apoplexy occurring shortly after the injury.*—(Traumatische spät Apoplexie). This condition, described by Bollinger ("Virchow's Festschrift," Berlin, 1891), comes on a few days or weeks after a head injury. The hemorrhage, which is fatal, takes place in the neighborhood of the fourth ventricle and the aqueduct of Sylvius. Bollinger maintains that the hemorrhage is preceded by local softening, which in turn has been caused by unequal pressure of the cerebrospinal fluid. This latter hypothesis remains to be proved for all cases.

The injury is invariably to the head. It may, or may not, cause unconsciousness. In any event the patient recovers, and is able to return to work. A considerable proportion of the cases have been in young persons. After a few days or weeks there begins headache, somnolence, and coma, with paralysis of the extremities, or of the cranial nerves, or, after the same period of freedom, an apopletic stroke may occur without any warning. Since the introduction of the term of traumatic late apoplexy, many cases have been described which the term originally was not intended to include. Such, for example, are cases of ordinary hemorrhage, secondary to laceration, and cases in which the blow or the shock attending it caused the rupture of preëxisting miliary aneurysms. These are not examples of *late* apoplexy. Also a variety of peculiar and non-fatal symptoms, such as attacks of somnolence, of stupor, of cranial nerve palsies, etc., are placed in this rubric, though that they should be here is a question of doubt.

3. *Apoplectiform symptoms occurring long after injury.*—The symptoms in this class point to a slow increase in vascular occlusion in parts long before the seats of traumatic insults, and are those of slow thrombosis. It is generally seen in cases of fracture of the skull, with extensive laceration of the brain. The increase in symptoms begins after a lapse of many years. The following cases illustrate the condition:

A man (reported by English, *Lancet*, 1904 sustained a compound depressed fracture of the vertex by being hit by a brick in 1861. The left leg was paralyzed, but recovered in a few weeks. Ten years later the leg again became weak, and finally almost completely paralyzed. The arm, also, lost considerable power, and the intellect became blunted.

Frost (*American Journal of Insanity*, 1903) reports the case of a man, who, twenty-six years after a compound fracture of the skull, with extensive loss of substance, slowly developed paralytic symptoms in the limbs of the opposite side. The autopsy showed general degeneration in the cerebral arteries, but more marked on the affected side of the brain. In this region, also, the brain showed cavities, the results of small areas of softening.

In conclusion, it need hardly be said, that these cases which have been mentioned are chiefly interesting from the standpoint of pathology and medical jurisprudence.

THE INDICATIONS FOR SURGICAL INTERVENTION IN CHRONIC GASTRIC ULCER.*

By FRANK H. MURDOCH, M.D.,
PITTSBURG, PA.

Fenwick, in his work on "Ulcer of the Stomach and Duodenum," has pointed out very clearly the anatomical and pathological distinctions between the acute and chronic forms of gastric ulceration. Acute ulcers, he says, are most common between the ages of fifteen and twenty-five; and occur more frequently in women than in men in the proportion of 10 to 1. Chronic ulcers rarely occur before the age of thirty and are more common in men than in women. In acute ulcer hemorrhage occurs as a first symptom in 75 per cent. of all cases; and perforation as a first symptom in 3 per cent. In chronic ulcer hemorrhage never occurs as a first symptom; but is most common between the first and fifth year of the disease. Immediately fatal hemorrhage occurs in only 3 to 5 per cent.; and perforation in 7 per cent. Acute ulcers are found most frequently along the upper margin of the stomach between the cardiac and the pylorus, and are multiple in 54 per cent.; whereas 76 per cent. of chronic ulcers are found at the pylorus on its posterior wall; and are solitary in 87 per cent.

Acute ulcers, as was long ago pointed out by Rokitansky, are punched out, and have a tendency to heal rapidly, leaving a small cicatrix. Chronic ulcers are apt to be funnel-shaped, and in healing are likely to cause cicatricial contractions and deformity.

*Read at a meeting of the Pittsburg Academy of Medicine.

The principal forms of chronic ulcer, according to Fenwick, are the following:

1. The gastralgic form, characterized by attacks of severe pain, resembling biliary colic.

2. The catarrhal or vomiting form, which may be confounded with acute gastric catarrh, hysteria, or uncontrollable vomiting of pregnancy.

3. The dyspeptic form, which must be distinguished from chronic gastritis and nervous dyspepsia.

4. The hemorrhagic form, which may be confounded with cirrhosis of the liver and thoracic aneurysm, in both of which diseases hæmatemesis may occur.

5. The cachectic form, characterized by emaciation, debility, and cachexia; so that it may be difficult to distinguish it from cancer or pernicious anæmia.

Leaving out of the question the sequelæ of chronic gastric ulcer, such as benign stenosis of the pylorus, hour-glass contraction of the stomach, perigastric abscess, etc., the indications for surigeal intervention and perforation and hemorrhage. Hemorrhage in acute ulcer is a common occurrence; but it seldom recurs because the edges of the sore are soft and yielding, the wounded vessel readily contracts, the bleeding ceases spontaneously and in a few weeks the ulcer heals.

Hemorrhage in chronic ulcer occurs in only about 18 per cent. of all cases; but when it does occur it is a much more serious matter than in the acute form of the disease, for the reason that the edges of the sore are fibrous and unyielding; the wounded vessel lies like a rigid pipe in the wall of the ulcer, and not being able to contract, the bleeding can only be stopped by a process of clotting. Here hemorrhage is very apt to recur either from insufficient clotting in the first place or from displacement of the thrombus (Fenwick). Therefore when hemorrhage occurs in chronic ulcer operation should not be too long delayed, as the bleeding is likely to recur again and again, at shorter or longer intervals, and will, without surgical interference, often result in the death of the patient. When perforation occurs an operation should be performed as soon as possible. Recently well-known English and American surgeons have advocated operation for the cure of the ulcer itself. Many heard the statement made by an eminent American surgeon in a very able paper read before this Academy in January, 1904, that Leube and Cramer in the treatment of chronic ulcer of the stomach advise washing the stomach out every day for four weeks, meantime feeding the patient by the bowel: and if at the end of that time there is no improvement they propose gastroenterostomy. Cramer[1] advocates this treatment in benign stenosis of the pylorus but not in ulcer. "In such cases"—that is, in dilatation of the stomach from benign stenosis of the pylorus—he says, "operation should be early advised, especially in the high degrees of stenosis, so that they do not lose too much time by internal treatment. If after four weeks of rational diet and gastric lavage no improvement is manifest, then do I in every case propose operation." Then he goes on to say that one has peculiar experiences. "I had," he says, "a man under treatment who had a stenosis of the pylorus from ulcer, and also a large secondary dilatation of the stomach. A rest cure of three weeks' duration brought about such a degree of improvement that we decided to at least defer the operation."

Schleip was the first to recommend washing out the stomach as a therapeutic measure in gastric ulcer. Leube, however, objected to this method on the ground that the sound might easily come in direct contact with the ulcerated portion of the stomach wall, and in this way lead to perforation or hemorrhage. Reigel[2] writes as follows: "I do not think that ulcer *per se* calls for treatment by the sound, as long as complications or sequelæ are absent. I consider this method of treatment altogether useless, and believe, moreover, that it may be dangerous under certain circumstances. In uncomplicated ulcer digestion proceeds in an altogether normal manner, as a matter of fact more rapidly than normal, chiefly owing to the condition of hyperchlorhydria that usually exists. Stagnation of food remnants therefore does not occur. Those who think it is necessary therefore to remove all acid from the stomach are wrong; all that is needed is to reduce the excess of acid. I do not see what good lavage of the stomach would accomplish under these conditions, for we usually remove the stomach contents either because there is decomposition or prolonged stagnation. In simple ulcer neither of these states exist."

Being unable to find in any publication that Leube recommends operation in all cases of gastric ulcer, if lavage and rectal feeding do not cure the patient in four weeks, I wrote to him in regard to the matter and he did me the great kindness to reply as follows: "The surgeon referred to probably meant that I consider an operation advisable if the ulcer is bleeding, and if this condition keeps on for weeks. If the patient has a bleeding ulcer I feed him by the bowel while the ulcer is bleeding, if the ulcer is not bleeding, usually not, or in any case only during the first three days of treatment. On the other hand I do not use the tube, or at least only in such cases in which there is heavy vomiting, and when I am fearing for the patient more from the vomiting than from using the stomach tube. The latter case, however, is very rare." In regard to operation for the cure of chronic gastric ulcer, Mansell Moullin[3] says, "I maintain that every chronic ulcer of the stomach that persists and causes serious pain and vomiting in spite of one thorough trial of the ordinary method of treatment should be exposed, examined, and treated surgically." Now what constitutes one thorough trial of the ordinary method of treatment? It usually means the Leube-Ziemssen rest cure, which extends over a period of from four to six weeks, and, while well adapted to the treatment of acute gastric ulcer, is not adequate for the cure of the chronic form of the disease, for the reason that it does not extend over a sufficiently long period of time. Fenwick says all clinical experience tends to show that even under the most favorable circumstances the disease requires many months for its cure, and that the mere subsidence of pain and vomiting is no proof that cicatrization has taken place. He divides the period of treatment into four stages: The first period lasts for two or three weeks, during which the patient remains in bed and has of course only liquid food. The second period lasts from the end of the second or third week to the end of the second month; during which time he advises rest if possible, the liquid food to be continued, with the addition to the milk of ground rice, flour, powdered biscuit or tapioca, clear soups, and expressed beef juice. The third period extends from the beginning of the third to the end of the sixth month. Although milk continues to constitute the staple diet, the patient may be permitted to have bread and milk, bread and butter, poached eggs, scraped and pounded raw meats, chicken cream, and broiled white fish, which has passed through a sieve. The fourth and final period should extend from the sixth to the twelfth

or eighteenth month, according to the severity of the case. During this time the diet is gradually increased until at its termination there are only a few articles which have to be prohibited. Milk then, according to this author, should constitute the chief articles of food for the first six months in the treatment of chronic gastric ulcer; and the diet should be carefully regulated for twelve months longer, making the total period a year and a half, during which the patient is restricted to those articles of food which are not difficult of digestion.

My own habit has been not to confine all patients to a liquid diet for a given length of time; but to be guided by the symptoms in each individual case. Some patients may be allowed solid food in two or three months, others not for five or six months, and two of my patients were obliged to live on liquid food for nine months. There is no danger, however, in continuing liquid food too long, the danger is in beginning solid food too soon. In regard to permanency or cure in chronic gastric ulcer under medical treatment, so far as I have been able to learn, in only two out of thirty-two cases which I have reported have the patients suffered from a recurrence of the ulcer. One of these was a man of intemperate habits; and the other was a domestic who would not follow instructions in regard to diet. Within two months past I have seen three of the patients who were treated in 1888-9, and have heard directly from two others; these are all enjoying excellent health, and do not suffer from any form of stomach trouble whatever.

In regard to the prognosis in chronic gastric ulcer under medical treatment, Lebert places the mortality at 8 per cent., Rosenheim at 20 per cent., but Leube found the mortality in 556 cases to be only 2.4 per cent. Fenwick observes that when the disease is taken in hand at an early stage and properly treated, the mortality does not exceed 4 per cent. On the other hand Haberkant found the mortality in gastroenterostomy for ulcer to be 25.5 per cent. Keorte, reported by Cramer, had seven deaths in twenty-eight operations, a mortality of 25 per cent. Rogers[4] says the mortality from gastroenterostomy now stands between 15 and 30 per cent., as given in the majority of statistics. Einhorn[5] states that among his own patients the death rate (from gastroenterostomy) has been nearly or quite 25 per cent., and Mitchell[6] reports six gastroenterostomies for benign stenosis of the pylorus with three deaths, a mortality of 50 per cent. Three of my own patients, and three others seen in consultation, have been operated upon in Mercy Hospital with one death, a mortality of 16.2 per cent. It is a well-established fact, therefore, that the mortality from gastroenterostomy is higher than the mortality from chronic gastric ulcer, when the patients have the benefit of proper medical treatment. As to the frequency with which stenosis of the pylorus follows chronic ulcer, Brinton computed that severe stenosis occurs in one out of 200 cases; and Fenwick believes the pylorus becomes partially obstructed in 16 to 20 per cent., when the ulcer is situated in its vicinity, but that in only about 2 per cent. of these is the stenosis extreme. In view, therefore, of the comparative infrequency of hemorrhage and perforation, which are the most common complications of chronic gastric ulcer, and of stenosis of the pylorus, which is its most common sequela requiring operation; and taking into consideration the high percentage of deaths from gastroenterostomy, and the low rate of mortality attending chronic ulcer of the stomach, it would certainly seem to be the part of wisdom to avoid surgical procedures as long as possible; and to resort to operation only when the indications for doing so are perfectly clear. What these indications are, has been pointed out by Deaver[7] in an article published in February, 1904, and so may be regarded as the latest authoritative statement on the subject. He does not advocate gastroenterostomy for the cure of the ulcer, but only for its complications or sequelæ. He says: "The one great indication for gastroenterostomy is found in all lesions of the stomach when the contents of the latter are not evacuated; whether this is due to a malignant or benign obstruction, an inflamed or ulcerated pylorus, or atony of the gastric muscle; the retained stomach contents must be provided for by an anastomotic opening."

In cases of stenosis of the pylorus when the stomach cannot empty itself of solid food, liquid diet should be tried. If this readily passes through the pyloric opening, and the patient can with comfort take sufficient nourishment to maintain him in a condition of health; and if he is willing to live on liquid food for an indefinite period, surgical intervention is not indicated, for should the stenosis ever reach such a high degree as to prevent the passage even of liquids, an operation can be done at any time; and it should then be done at once, as the only means of saving the life of the patient.

PECULIAR NERVOUS SYMPTOMS FOLLOWING OPERATION.*

By W. R. BLAILOCK, M.D.,
MCGREGOR, TEX.

THE patient, an unmarried woman, aged twenty-two years, of large frame, rather fleshy, weight 180 lbs., a liberal eater; often constipated. Father was an invalid for several years, perhaps had tuberculosis, finally suffering an aberration of mind, wandering into a forest and dying alone. A paternal aunt had an attack of incipient insanity but recovered and is now quite well. Patient has a brother and two sisters who are in good health, except one sister who suffers considerably at her monthly periods. Up to the age of twenty years the patient enjoyed good health, but at this time the monthly flow became excessive, growing worse month by month until it became almost continuous. I saw her in October, 1903, when she had been in her room several weeks. Every time she took exercise hemorrhage followed. On examination the uterus was found slightly enlarged and immovable, the depth being three inches. A slight enlargement of the right ovary and tube could be detected, and marked tenderness but no enlargement of the left ovary. Curettage was done, but the amount of diseased endometrium was quite insignificant. Pure creoline was applied to the endometrium, and in a few days all discharge ceased. For two months there was no recurrence, and when the discharge did return it was a normal menstruation lasting about six days. In February, 1904, she had a hemorrhage which was continuous up to March 14, 1904, at which time she returned for further treatment. On examination the ovaries and tubes were found in the same condition as at the

*Read before the McLennan County (Texas) Medical Association.

previous examination, but the depth of the uterus was only two inches. Weight had not diminished; appetite good; bowels constipated. A uterine sedative was given, and cascara to correct constipation. Scanty diet and active exercise were advised to reduce flesh. For two weeks there was no discharge; she felt well and was preparing to return home when another hemorrhage worse than any previous one came on. She now gave up all hope of getting well without an operation, and asked me to do whatever was necessary. On March 31, thinking her condition favorable after the most rigid precautions to secure asepsis. I did, or rather attempted, a curettage, the cavity being too small to admit of a satisfactory operation such as I had previously made. I wore rubber gloves which had been previously washed with potash soap, boiled, soaked twenty-four hours in 1 to 250 bichloride solution, then kept in 1 to 1000 bichloride solution.

After the curettage the gloves were removed and my hands, which had been previously sterilized, were washed in hot salt solution. (A full description of the sterilization of the gloves is given because they had previously been used with a septic case.)

A median incision was made about four inches in length between the umbilicus and symphysis. The abdominal wall, mostly fat, was nearly three inches thick. After breaking up some adhesions I found the fundus of the uterus wedged in under the bladder; on following the tube on the right side, which was perceptibly enlarged, I found a cyst, between a turkey's egg and a hen's egg in size, occupying the site of the ovary. After protecting with gauze pads, an effort was made to bring the cyst up into the incision, but owing to adhesions this failed. In breaking up these adhesions the cyst ruptured, but its contents were caught on the gauze pads and removed. The specimen shows the rupture in the cyst and also the tube with some smaller intraligamentary cysts lying along its course. It will be seen that the tube is enlarged. Passing the finger along the left tube, which was not enlarged, a small indurated mass was found which felt more like a pebble than an ovary; it proved to be the left ovary, and it was removed and is shown in photograph. There was very little loss of blood, and as I had the best assurance that the operative field was aseptic, I did not use drainage.

During the operation, which lasted one hour, including curettage, less than one ounce of chloroform was used. Before the patient was removed from operating table she vomited bile, and this was kept up at intervals of two or three hours. Four ounces of salt solution were thrown into the rectum every four hours, and on the second day a cup of warm water was given by the stomach to clean it out. The kidneys acted freely; forty-eight hours after operation three grains of calomel in powder were given. Vomiting continued, but she retained most of the calomel. Fifty-six hours after operation an enema of nearly one gallon of warm soapsuds was given; a very fair action was secured. Vomiting continued, the color of the vomit had changed from a dark green to a chocolate brown; a heaping tablespoonful of sulphate of magnesia in a glass of water was given; this was only in part retained, but a good through action was secured.

Three times each day $\frac{1}{30}$ grain of strychnine was given hypodermically and one dose of $\frac{1}{6}$ grain of morphine, on the night following operation. After the bowels acted, chicken essence with liquid peptonoids were given by rectum; water in small quantities by mouth was tried but badly borne. The pulse at first was 105, came down to 90, and on the second day was 85; temperature during the first twenty-four hours reached 101°, but came down to 99.5°; skin color good, abdomen soft on both sides, no gas in bowels.

Posterior aspect of the right ovary, tube, a portion of the broad ligament, and a small indurated left ovary; A, right tube cut near cornu of uterus; B, small intraligamentary cyst; C, cotyledon-like process with small cyst on end; D, tumor involving the entire right ovary; E, rupture made in cyst while attempting its removal; F, sclerosed left ovary, the part below the tranverse fissure giving the sensation to touch as stone.

Seventy-two hours after operation the patient, who had been reasonably cheerful, said she was going to die, and there were slight twitchings, not confined to any special muscles. Three hours afterward she went into a state of unconsciousness, the right leg and arm were extended, the left was drawn up, the pupils were normal, jaws locked, the masseter muscles being very hard; the under lip was caught between the teeth several times and bitten; it was very difficult to separate teeth. When she was allowed to be perfectly quiet for a while the lower jaw would drop, the masseter being relaxed, but as soon as she was touched a violent closure of the jaws would take place. The conjunctivæ were getting yellow, having been white up to this time; pulse 86, temperature 99°. The dressing was removed and wound found in excellent condition, union by first intention was assured. There was no rigidity of the recti or any of

the abdominal muscles; respirations 18 per minute, full and deep, with occasional sighing and gaping. Vomiting less frequent, but vomited matter still dark to black. Eighty-five hours after the operation the pulse rose to 130 beats per minute, patient was very restless, but still lying on her right side, jaws locked, skin becoming yellow, kidneys not acting freely, urine high colored and had to be drawn, reaction acid, specific gravity 1024, urea 2½ per cent., no albumin, sugar, nor bile. Culture of both blood and urine were made on glycerin agar and blood serum at this period, the result of which will be given later on. A blood count showed 3,950,000 red blood globules per c.mm. and 1 white to 400 red, or 9875 per c.mm. Fresh blood stains showed no parasites or any other pathological condition. As the rectum had become intolerant of fluid and as none could be given by mouth, I resorted to hypodermoclysis, using 1½ pints of physiological salt solution; after which the pulse came down in the course of six hours to 105 beats per minute. Hypodermics of the salt solution were given each day for four days, except one day it was used twice. Each time after it was used she became quiet. As soon as the rectum would bear it, concentrated food was given, and often one or two tablespoonfuls of whiskey added; an occasional dose of 5 grains of chloral was also added. Once a day, at night, $\frac{1}{60}$ grain of strychnine and $\frac{1}{20}$ grain of morphine were given hypodermically, which kept her quiet. On the eighth day after the operation she regained consciousness and began to take water and food by the mouth; pulse 65, temperature 98.5°, tongue clean, eyes still yellow, skin cleared up, bowels and kidneys acting well. The blood cultures gave negative results, the urine only bacteria. Sutures were removed on the tenth day and union found perfect. The only thing to mar the smooth course of convalescence was an abcess of the left gluteal region where the salt solution had been injected. The first pus from this abscess was very dark, almost black. The water and salt were sterilized each time in an Arnold sterilizer, except once plain boiled water with salt added before boiling was used.

The patient was never hysterical, with one exception, and never had had any disturbance of the mind except that already stated. The exception was during the month of January, 1902. She was teaching, and has a very faint remembrance of what transpired for one week. The temperature was never above 101° and only that high for a short time; the abdomen was never typanitic or tender; the incision healed perfectly by first intention. Careful cultures of the blood and urine in forth-eight hours at body temperature gave bacteria for urine, nothing for blood; at the expiration of six days the results were the same. On the fourteenth day a colony of staphylococcus pyogenes aureus on the serum from blood, and of staphylococcus citreus on serum from urine. Just how long these colonies of staphylococci required for development is not known; the cultures were all kept at body temperature for forty-eight hours, after which they were kept in a warm room.

Was this a case of sepsis? In the septic cases that I have seen there is high temperature and a greater acceleration of pulse than in this case, besides in this class of cases, if septic, rigidity of abdominal muscles, tympany, quick and irregular pulse, high temperature, scanty and high colored urine are apt to occur. The early and persistent vomiting is, however, present in sepsis to a great extent. If streptococci, or bacilli of any kind, were in the blood they did not develop under the most favorable conditions, to wit: glycerin agar and blood serum at body temperature. The urine gave bacteria just as any healthy urine would. The blood count proportion of white to red blood cells, the character of the cells, and lastly (a fact which has not yet been mentioned) the percentage of hæmoglobin, which was above 90 per cent. on the tenth day after operation, did not indicate blood disintegration. I think, notwithstanding the two weeks of preparatory treatment, the liver was loaded with bile, which excited vomiting, the frequent repetition of which caused passive hyperæmia in the brain, resulting after three full days in extension of one arm and leg, contraction of the other arm and leg, and contraction of the masseters with unconciousness but not sufficient to produce coma.

The administration of salt solution, the daily dose of strychnine with $\frac{1}{20}$ grain of morphine, the injection of whiskey into the rectum, with concentrated food, were all designed to secure and maintain a steady and uniform heart action, thus preventing further stasis in the brain. Small doses of chloral by rectum, to secure quiet in the intervals between hypodermics of salt solution and of strychnine and morphine were given once a day. The mind now, nineteen days after the operation, is perfectly clear, all discharge from the uterus has ceased, and the patient is sitting up part of every day; the eyes have fully cleared up and she feels perfectly well. Perhaps if a calomel purge had been given during the preparatory treatment and phosphate of sodium given three times a day for a week, she would have done better.

What, if any, influence inherited tendency to brain disease had I do not know, but it seems reasonable to suppose that it was a factor. The complete and almost sudden return of the mental functions and the restoration of symmetry in the limbs are conclusive to me that no rupture of vessels occurred in the brain.

Note.—May 9, the patient is perfectly well, has no vaginal discharge, the mind is clear. She wears an abdominal bandage and goes around her home at will.

SOME THOUGHTS CONCERNING TWO RECENT CASES OF ECTOPIC GESTATION.*

By A. BROTHERS, B.S., M.D.,
NEW YORK.
VISITING GYNECOLOGIST TO BETH ISRAEL HOSPITAL; ADJUNCT PROFESSOR OF GYNECOLOGY, NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

It is a curious experience with me to meet ectopic gestation in groups of cases. Thus months may elapse without a case of this kind coming my way and then, two, three, or more will appear in rapid succession. So fascinating to me is the subject, that although I have now a list of over forty cases operated on by myself, each new one seems to present something of fresh interest. Hence, I take the liberty of submitting to-night the histories of two cases, which I saw within forty-eight hours of each other, about a month ago, and which have given me fresh food for thought.

Case I.—The patient walked into my office on March 16, 1904, with a request from a physician to take her into my service at the hospital and perform a curettage. She gave the following history: Mrs. J. S. Russian, æt. twenty-four, married seven years, one child six years ago. Five years ago she was curetted for metrorrhagia. Her husband came to this country three years ago and she followed nine months later.

Her menses were fairly regular, but always showed a slight tendency toward delay. Her last menstrual period was delayed longer than usual—namely, for three weeks. One month previously (after an absence of her menses for seven weeks) she began to suffer from uterine bleedings, which

*Read at a meeting of the Society of Alumin of Bellevue Hospital, May 4, 1904.

continued down to the time of her visit. The losses of blood were very considerable. Two weeks previously she had had an attack of violent abdominal pain for which a physician was called. During the attack she felt weak, but did not faint. When the doctor arrived she felt better. No hypodermic medication was necessary, and the doctor simply prescribed some pills without venturing an opinion as to the nature of the ailment. The pains at this time were general, but kept on in a mild degree, and were located mostly on the left side. A week previously a small bit of tissue was expelled from the vagina which did not seem to resemble the usual blood-clots.

The pelvic examination of this woman revealed a small anteflexed uterus deflected to the right and connected along its left border with a soft, moderately sensitive tumor, the size of a hen's egg.

The diagnosis of unruptured ectopic gestation with a tendency to tubal abortion was made and the patient frankly told that a curettage would not be done. She consented to submit the entire operative progam to my wishes.

On March 18, 1904, under anæsthesia, the uterine interior was explored with a sound and curette and found to be about normal in size and entirely empty. An abdominal incision was then made along the outer border of the left rectus muscle, and (after drawing the muscle inward toward the median line a distance of a half inch or so) the peritoneal cavity was opened. The unruptured tubal sac, with its corresponding ovary, was removed—the few adhesions due to a recent peritonitis being readily separated. There were not more than a half dozen small black clots and no free blood in the peritoneal cavity. The right adnexa were not enlarged but were so firmly bound down by old adhesions that it was thought best to leave them undisturbed. The patient reacted beautifully after the operation. Examination of the tumor showed the fimbriated end to have been completely obliterated. The specimen shows an unruptured tube with its contents intact.

In reviewing this case we note the following similarities to the usually accepted symptoms and history of ectopic gestation.

1. The six years of sterility succeeding the birth of her first child.

2. The preëxisting pelvic disease which required a curettage five years previously.

3. The suspension of menstruation for a period of seven weeks.

4. The succeeding uterine bleedings during an entire month.

5. The attack of general abdominal cramps suggesting a beginning tubal abortion and accounting for the black clots found in the peritoneal cavity at the time of operation.

6. The tendency to syncope during this attack.

7. The localization of the pain for the most part in the left pelvis.

8. The discharge of probably decidual tissue a week previous to operation.

With these symptoms and facts tabulated there could be little fear, in connection with a soft unilateral pelvic tumor, of risking the diagnosis of ectopic gestation. And still one of the best general practitioners in this city overlooked the condition, and for three reasons: (1) because it did not occur to him to think of ectopic gestation in this individual case; (2) because, for certain unknown reasons, he was unable at the time to map out the pelvic tumor; (3) because of the fact that, with the exception of one or two days, this patient was not confined to bed and suffered so little that she came to the doctor's office for treatment as an ambulant patient. In other words, the case was so mild and the patient presented so few symptoms that so serious a condition as ectopic gestation was not even suspected.

Case II.—On March 18, 1900, I was requested by a colleague to examine Mrs. H. S., thirty-nine years old. She gave a history of having been married twice—three years to her second husband—but of never having conceived. During eleven years she had been a widow.

At thirteen she began to menstruate. For a year previously she had been somewhat irregular, so that it was not unusual for the period to be delayed a few days or weeks. Her last menstruation was one week overdue, but this attracted no especial attention. Two weeks previously she was taken with abdominal cramps and bleeding from the vagina, which lasted thirteen days. She had no fainting spells. The bleeding had ceased nine days previous to her operation.

When I saw her in consultation at her home she had been confined to bed for several days and had had a temperature of 101.5° F. (rectal) with a pulse of 88. There was no suggestion of acute anæmia about her skin or mucous membranes. The face was drawn and anxious. She complained of intense general abdominal pains. The abdomen presented the characteristic appearances of acute general peritonitis. Tympanites was excessive and the entire abdominal surface up to the costal arch was exquisitely tender. A local vaginal examination revealed a doughy mass behind the uterus.

The differentiation between a general peritonitis dependent on an old pus-tube suddenly ruptured and one dependent on an ectopic gestation could not be made without the aid of an aspirating needle introduced into the retrouterine mass. The doctor declined to resort to this procedure and preferred to turn the woman over to my care at the hospital.

Fortunately, perhaps, for the patient there was a delay of two days in getting her admitted to the overcrowded hospital, and when she got there I found that there was a marked subsidence of the tympanites and tenderness over the abdomen although the mass in Douglas's cul-de-sac was still quite clearly present. Her temperature was normal and she was fairly comfortable. Under the circumstances I decided to wait and get away a little further from the general peritonitic manifestations. After three or four days I decided to operate.

Under anæsthesia I passed an aspirating needle into the now clearly fluctuating mass behind the uterus and drew off dark liquid blood. Her position was now changed to that of Trendelenburg and a laparotomy was done. The intestine was very much inflated and there were numerous adhesions between the omentum and the pelvic structures. There was no free blood in the peritoneal cavity. After slow and tedious work it was possible to get the intestines and omentum sufficiently out of the way to inspect and palpate the pelvic organs. The uterus was small. The right adnexa were not enlarged and were buried in old adhesions which could not readily be separated. On the left side a tumor, apparently the size of a baseball, was felt dipping down to the depths of the cul-de-sac of Douglas. By the sense of touch the mass was gently separated from its surroundings and found to be the distended left tube arching behind the uterus. At its lower border was an hæmatocele which was ruptured in removing the tube, its contents (a certain amount of black blood and clots) escaping. The tumor was clamped off at its uterine and pelvic attachments and removed. The specimen consisted of the tube filled with blood, and showed a raw area on its

lower surface which had evidently been the seat of a rupture and had produced a shut-off intraperitoneal collection of blood (hæmatocele) in Douglas's cul-de-sac. After the usual intraperitoneal toilet the wound in the abdominal wall was closed without drainage. This patient also made an uninterrupted recovery.

The case is instructive as showing a woman who had been married twenty-two years previously and who had never conceived until the third year of her marriage to her second husband. She had then become pregnant in a diseased tube which had ruptured at an early period of gestation. The differentiation from a pelvic abscess was only possible in this case by means of the hypodermic needle. I am satisfied that the peritonitic manifestations in this case—had the diagnosis of ectopic gestation been possible at once—would have led most gynecologists to infer that there was free hemorrhage going on in the general peritoneal cavity and no delay in operating would have been tolerated. As a matter of fact there was no free intraperitoneal hemorrhage going on in this case, and the delay of a number of days made all the difference between operating in the presence of acute peritonitis and of operating after the immediate manifestations of peritonitic irritation had subsided.

The two specimens bring up a few further reflections concerning the subjects of unruptured tubal pregnancy, tubal abortion, and ruptured tubal pregnancy.

The specimen of unruptured tubal pregnancy shows that the fimbriated end of the tube being totally occluded and the ovum continuing to grow there, the case could have had but one termination, and that is rupture of the thinned wall of the tube with the probability of a fatal result.

This rupture of the tube after occlusion of the fimbriated end is shown to have actually occurred in the second specimen. Fortunately for the patient, the rupture occurred on the lower surface of the tube, and the collection of blood was rapidly walled off by peritonitic adhesions and shut off in Douglas' cul-de-sac. This patient might have died from the same accident had the rupture taken place from the upper or lateral portions of the tube instead of its under surface. As a matter of fact she was much safer or better off than the other woman with the unruptured tube, in whom the possibilities of the future were yet undetermined. Indeed she might have been pronounced entirely free from danger—excepting possibly that of suppuration of a pelvic hæmatocele—could we have pronounced the ovum absolutely dead. In the present state of our knowledge we have no means of determining the death of the ovum, embryo, or young fœtus, except by the measure of time—and this means is (by itself) too often a source of grave danger.

This brings us to the consideration of the question "What are nature's methods of curing ectopic gestation?" It is almost needless to tell this audience that many cases of ectopic gestation are cured by nature and that a preponderating number of medical men throughout the world rarely if ever meet a case of ectopic gestation. Do I hurt the feelings of my medical colleagues when I state that I believe this is due, first, to the fact that the diagnosis has not been made, and, secondly, to the fact that under the usual rest in bed prescribed for the assumed abortion from which the patient is apparently suffering, the woman recovers spontaneously? If I tread on anybody's toes by this statement, I njure at the same time my own pedal digits because I confess that, at one period in my career as a general practitioner, I passed ten years without meeting a single case, and that, in the succeeding ten years, I have opened the abdomen and confirmed my diagnosis of ectopic gestation in a considerable number of cases. I may add that I have observed a number of cases in recent years (one particularly comes to my mind in which my friend Dr. Boldt agreed as to the diagnosis of ectopic gestation) in which my patient got well without operation and subsequently gave birth to children.

It therefore being positively established that certain cases of ectopic gestation do end in spontaneous recovery, how, we may ask, is this accomplished? By one of three methods: (1) Either the ovum dies in the tube, choked off in its own clot and the hæmatosalpinx subsequently becomes absorbed; or, (2) after a tubal abortion the escaped ovum or embryo perishes in the hemorrhagic intraperitoneal effusion; or, (3) the same result follows after a tubal rupture.

Could we determine in unruptured tubal pregnancies or after tubal abortion with certainty that embryonic life had ceased, our course of procedure would be fairly clear. We should then intelligently—and not accidentally, as is so often the case at present—decide on leaving the case to nature. Indeed, certain writers on gynecology advise this course of procedure in many cases, although my experience has been that they seldom follow it up in practice. On the other hand, the progressive growth of the ovum or fœtus in the earliest months of pregnancy just as clearly indicates prompt surgical intervention—and preferably before rupture has taken place.

To be able to differentiate, then, the cases with a dead ovum from those in which the ovum has life, would indeed mark an era in the diagnosis and treatment of ectopic gestation. It certainly would reduce the number of laparotomies for this cause which every one of the few thousands of abdominal surgeons meets throughout the world every year. But you say, why not kill the ovum or embryo? This may be one of the possibilities of the future, but is really not looking forward, but backward. For I need not tell you that less than twenty years ago the destruction of the ovum, or fœticide, by means of electricity was a method frequently resorted to in this country, and that morphine injections into the gestation sac was in vogue on the continent.

The statistics which I collected some sixteen years ago showed only one death in some forty cases after the use of electricity. But I am now satisfied that desperate cases with large ruptures and collapse were not included in these figures, and accounted for this extraordinarily good showing. I mention the treatment only as a matter of historical interest, for I know that in the hands of certain men the mortality rate of all kinds of cases, including the most desperate, has been less than 5 per cent.

Hence we must continue to reject all methods which aim at the artificial death of the ovum or embryo so long as twentieth-century surgery can boast of such results as above stated. We must continue to feel ourselves justified in operating upon women who might have got well without operation. For I do not believe that a woman ever did get thoroughly well after having had an attack of ectopic gestation any more than a person with appendicitis ever thoroughly recovered spontaneously, a more or less diseased appendix always being left. In other words, the same reasons which induce the general surgeon to-day to remove the appendix during or after an attack of appendicitis apply to the abdominal surgeon when he removes the pathological Fallopian tube during or after ectopic gestation,

and this applies equally to the three conditions above referred to, namely, unruptured ectopic gestation, tubal abortion, and ruptured ectopic gestation.

Why not treat the pelvic hæmatocele alone? I have treated two cases. In one suppuration occurred and left the woman with a pelvic tumor. The other left no tumor, but left the patient more or less of an invalid. Therefore if such cases are not to be left exclusively to nature for absorption, I have little faith in incision and drainage of a pelvic hæmatocele which leaves the diseased tube in the woman's pelvis—unless as a palliative procedure. I look on it as most surgeons would regard the opening and drainage of an appendicular abscess, leaving the appendix as a source of possible future trouble. Under all circumstances it should be regarded only as a temporary procedure, and one called for by special circumstances and not as a real cure.

ŒSOPHAGEAL DIVERTICULUM; DIAGNOSIS CONFIRMED BY X-RAY EXAMINATION.*

By H. A. BERNSTEIN, M.D.,
NEW YORK.

Medical and surgical literature of to-day, teems with examples of tumors, ulcers, and eruptions treated with varying success by means of the *x*-ray. Examination of bones, and the locating of foreign substances in the tissue of the living body dates almost from the time of the discoveries of Röntgen. The examination of the lungs and other organs and soft tissues, in search of morbid processes, is of more recent origin, but cannot at present be considered entirely new. I wish to present a method by which an œsophageal diverticulum was examined for the purpose of determining its extent and location; and incidentally to verify the diagnosis.

About two years ago a gentleman presented himself to me for advice. He had been under my treatment some two years before for facial erysipelas from which he made a rapid and complete recovery. The one symptom which caused him the most distress during this illness, was his inability to retain food; this I attributed (and I believe rightly) to the conditions attendant upon pyrexia and the intoxication of the disease. He had several subsequent attacks, from which he recovered with equal, if not greater, rapidity, and during which he complained of similar gastric disturbances. He passed from my care and had almost been forgotten by me, when he made his appearance as before mentioned. The change that had taken place since I last saw him was so great that I did not at first recognize him. He had lost nearly seventy-five pounds in weight, and seemed almost like a shadow of his former two-hundred and odd pounds. He explained his absence by the fact that he had been abroad, and while sojourning in Germany he developed, what was diagnosed by the physician attending him there, as "catarrh of the stomach." He underwent treatment in Germany and Austria, visiting the various health-resorts and watering-places in search of relief. His symptoms gradually growing worse, he returned to this country to settle up his affairs and await the outcome of his illness. His history was as follows: Age sixty-two years; nativity, Germany. He had never complained of any serious indisposition before his first attack of erysipelas. Parents both had passed the allotted three score and ten. Brothers and sisters alive and in good health. No history of cancer or tuberculosis in the family. Examination of the patient showed heart and lungs sound and normal. No enlargement of the liver or spleen. Temperature 98.4°; urine, acid, sp. gr. 1020; no albumin, no sugar. General health was good, and all the functions of life were normally performed. He had no pains of any kind and complained only of inability to retain food, and the general weakness and loss of flesh which naturally followed. His appetite was good, in fact abnormal, but of late he had confined himself mainly to liquid and semi-liquid food. He had been put upon some sort of diet by the physicians who handled his case in Europe, from which he claimed to have had some relief. But to size up his case in a general way, he appeared like a person in want of nourishment. While talking to me he said he had a desire to vomit. I grasped the opportunity to examine the contents of his stomach, and handed him a bowl for that purpose. The vomitus consisted of an undigested mixture of eggs, oatmeal, and a brownish fluid. The whole having rather an odor of coffee. He admitted having eaten and drank these articles about an hour before, and said that he always evacuated the greater part of his food in this same manner about an hour after eating or drinking. The vomitus did not show acid reaction to litmus-paper test, and my first impression, which proved to be correct, was that it had not been in the stomach at all. I attempted to pass a stomach tube, but was unable to insert it further than eleven inches from the teeth. Repeated attempts always yielded the same result. He was instructed to call again the following morning before having taken any food or drink. Upon his second visit I again attempted to pass the tube but had no better success. I then requested him to drink as much water as he could, giving it to him glass by glass. He succeeded in drinking three tumblerfuls when the whole amount was rejected into a bowl which I had prepared, thus enabling me to remeasure the amount. Upon examining the patient, I found no displacement of the larynx, and no tumor was to be discerned on palpation, nor did pressure produce dyspnœa. The diagnosis was "stricture of the œsophagus with a possible diverticulum."

The patient consulted several physicians and various opinions were offered. Some pronounced malignant growth the cause, though no tumor could be discovered, and they were puzzled at the entire absence of pain, but the age of the patient was taken into consideration. The diagnosis of stricture and that of an œsophageal diverticulum was made. It had been proposed that the patient be fed while in a recumbent position, and that he remain lying for an hour after eating. This was done and supplemented by rectal feeding. An *x*-ray examination was suggested, and for this purpose the patient was to be given a large quantity of sub-nitrate of bismuth, and an attempt was then to be made to take a radiograph while this substance remained in the œsophagus. The subject became intensely interesting, and grew more so as time advanced and the case developed. The patient retained more food in the recumbent position, and the nutrient enemata seemed to give him added strength. For a time he got along fairly well, and though he did not gain in weight neither did he lose. At this time the patient refused to consider any surgical procedure, or even a consultation with that purpose in view. However, the time soon arrived when even in the recumbent position food failed to pass into the stomach, and he had to depend on rectal feeding for sustenance. *X*-ray examinations and radiographs with bismuth failed utterly. Sufficient was never retained long enough by the patient to be seen upon examination. At one time nearly five drachms were swallowed but almost immediately rejected. I then procured a large, soft rubber

*Reported at a meeting of the Harlem Medical Association.

catheter, closed one end, and filled the tube with bird-shot. The patient swallowed the catheter in the same manner as when passing the stomach tube, to which he had grown quite accustomed. He could not, however, retain the catheter long enough for me to examine him. The patient was instructed to swallow a soft catheter three or four times daily, until his fauces and pharynx were less sensitive to its presence, and until he could retain it for ten minutes. This he succeeded in doing in about six days. He was then placed in position before the *x*-ray tube, and with an exposure of ten minutes I succeeded in getting a rather poor radiograph of his neck and chest, with a faint outline of the contained catheter. A few days later, I made another attempt to procure a picture with similar bad and unsatisfactory results. The picture on the fluoroscopic screen, however, was perfect, and the catheter could be distinctly seen curled upon itself in U-shape, and evidently outlining the pouch. The base of the diverticulum appeared to be on a level with the upper margin of the second rib in the back. The patient by this time was steadily losing ground and welcomed anything for relief. A demonstration with the *x*-ray was made at my office, at which Dr. Irving S. Haynes and a number of other physicians were present. Of the various operative measures discussed, gastrostomy was favored, and was performed by Dr. I. S. Haynes at St. Mark's Hospital. The hope was entertained that at a later date a second operation could be done, with better chances for the patient. The stomach, on being opened, was found to be entirely empty. A gastric fistula was established and the patient went on toward recovery. Arrangements had been made to have the patient removed to his home within a few days, when on the ninth day after the operation, one of those unfortunate accidents occurred that cannot be foretold. The patient was stricken with hemiplegia due to cerebral embolism, and died two days later without regaining full consciousness. The family refused to permit autopsy, but nevertheless the diagnosis of a diverticulum is sustained by all who saw the catheter as it lay curled in the œsophageal sack or hernia, to the right of the spinal column.

77 West One Hundred and Eighteenth Street.

Cancer and Uric Acid; or, Uric Acid as a Cause of the Irritation Which Predisposes to Cancer.—Alexander Haig sums up the points of his paper as follows: Cancer tends to affect seats of local irritation or ulceration. Uric acid is responsible for more widespread and chronic local irritation in all the tissues of the body than any other known substance. Insurance statistics seem to show that cancer is increasing side by side with many other diseases which are no doubt due to uric acid, as more and more uric acid is poured into the body in flesh, soup, meat extracts, tea and coffee, all of which are consumed much more largely at the present day than they were thirty years ago. Natives of countries where the diet is, to a considerable extent, uric acid free, suffer but little from cancer. While there is some evidence tending to show that when uric acid is present in excess, first in the diet and, as a result, in the blood, the incidence of cancer is increased by substances which tend to precipitate uric acid in the tissues and is diminished by substances which aid its solution and removal from the body. The writer believes that if further statistics support those given above, that we need not wait to find a possible parasite, but can at once diminish the destructive power of cancer by cutting off supplies of uric acid and giving solvents.—*The Medical Press and Circular.*

A Case of Estivoautumnal Malarial Fever with Parasites of an Unusual Type.—J. Odery Symes reports a case of this nature which is of interest primarily on account of the unusual type of organism present. It also illustrates the necessity of a microscopical examination of the blood in all cases of malaria, and the futility of treating cases of estivo-autumnal malaria by quinine alone. In the fresh blood numerous small intracellular non-pigmented parasites were seen, together with very many crescentic and ovoid bodies. The pigment in the crescents and ovoid bodies showed very lively movement, and this continued for more than an hour after the blood had been drawn. Flagellate bodies were observed to bud out from the ovoid bodies and to move away in the serum. The peculiar feature of the blood was the presence of sausage-shaped parasites with scattered pigment lying within the red cells and of cigar-shaped parasites lying across the corpuscle with their ends projecting beyond the periphery. Such forms of parasites have been described by Rowley in the *Johns Hopkins Hospital Bulletin.* Stained films showed the same forms, but the sausage-shaped bodies did not entirely preserve their original shape. Rowley thinks that possibly this elongated parasite is developed from ring-worms, and is designed ultimately to become a crescent.—*Bristol Medico-Chirurgical Journal.*

Alcoholism and Heredity—Macpherson says that the first point of resemblance between alcoholism and the neuroses is its heredity. When we talk of hereditary tendency to inebriety, we mean, of course, that the peculiar constitution which craves for an artificial mental state is inherited. Now this peculiar mental consitution is not produced by the drinking habits of the parents, for, as we have seen, descent is through the germ cells alone. But during the tenancy of the germ cells in the parental body do they not receive such and such impressions? Probably they do, but to assert that these impressions are conveyed as definite-like propensities to a future individual is contrary to the latest knowledge of the subject. This craving for intense states of consciousness goes back as far as we can trace the history of the race, and exists among primitive races at the present day. It would only be wasting time to recount the details of the generally accepted heredity of alcoholism, but is it an important fact to notice that heredity is as often dissimilar as similar—that is to say, that alcoholics are closely related to every form of insanity, to the neuroses, and to many of the diathetic diseases. Legrain says that we find all forms of insanity present in the ancestors of drinkers—mental-defect, hysteria, epilepsy, mania, melancholia, periodic insanity, general paralysis, brain softening, and apoplexy—*Edinburgh Medical Journal.*

The Silver Bolt as a Means of Fixing Ununited Fractures of Certain Long Bones.—Stephen H. Watts describes this method as being by no means perfect, but it is used for want of a better one. It was tried in the case of a patient who had suffered from a very bad compound comminuted fracture of both bones of the right lower leg, and a compound fracture of the left femur. The right leg had to be amputated. The left femur was treated for some weeks in plaster but no union took place. Two months after the injury, the ends of the fragments, which overlapped several centimeters, lay in a definite sac filled with clear fluid, evidently an early stage in the formation of a false joint. The sac was excised, the bones mortised step-wise, care being taken to preserve as much periosteum as possible, and the silver bolt inserted in an antero-posterior direction. The nut was screwed down and the projecting part of the bolt cut off. The fragments were thus held firmly in good position. The skin wound was sutured with silver wire, a small drain of rubber tissue being placed down to the site of the fracture. The mortise was so made that the projecting part of the lower fragment lay anterior to and so rested upon the projecting part of the upper fragment. Three months after the operation it was interesting to note that whereas a few degrees of lateral motion was possible at the site of fracture, no motion was possible in an anteroposterior direction—that is, in the direction of the shaft of the bolt. A month later the fragments were united.—*Bulletin of the Johns Hopkins Hospital.*

FILTRATION OF WATER AND TYPHOID FEVER.

THAT efficient filtration of water has a remarkable influence on the prevalence of typhoid fever is a fact too thoroughly substantiated to admit of refutation. Another point sufficiently obvious to those who will take the trouble to investigate, is that it is largely owing to the neglect in the United States of taking these precautions that typhoid fever occurs so frequently in this country.

Dr. Joseph D. Craig, writing in the *Albany Medical Annals* for August, discusses the question, and shows that in those cities in which sand filtration of water, or the conveyance of water from uncontaminated sources, is in vogue, the occurrence of typhoid fever is rare. For instance, in the city of Munich, from 1851 to 1859, before the introduction of an improved water supply, the typhoid deaths were 21 per 10,000 deaths from all causes, and from 1874 to 1884, after the introduction of an improved water supply from springs thirty-seven miles from the city, fell to 6.4 per 10,000 total deaths. In the city of Berlin, from 1884 to 1872, previous to the purification of the water supply, the typhoid deaths were 9.2 per 10,000 deaths, but when the water supply was drawn from lakes, the water of which was afterward filtered through sand, the deaths fell to 2.9 per 10,000 total deaths.

A comparison between the city of Chicago using lake water without filtration and the city of Berlin using lake water subsequently filtered through sand is especially instructive. Chicago reduced her typhoid rate from 159, in 1891, to 46 per 100,000 population, by providing a less contaminated water supply, while Berlin, which had a typhoid death rate of 9.2 per 10,000 total deaths before improving her water supply, had, as a result of using lake water, afterward filtered through sand, a reduction of her typhoid deaths to 2.9 per 10,000 deaths. Or, expressed in terms of population, Chicago, from the last available statistics, showed a death rate of 46 per 100,000 population, and Berlin 5 per 100,000.

Dr. Craig gives two striking examples of the manner in which the drinking water supplied to communities can become infected with the typhoid fever germs even, indeed, from a single case of the disease, if the water supply be not protected by filtration or by other means.

"The village of Lausanne in Switzerland suffered from an outbreak of typhoid fever in 1872, before which time not even a single sporadic case of the disease had been known. After that date and before the disappearance of the disease, 17 per cent. of the inhabitants had been attacked. Without presenting all the evidence, which at each step seemed to be fully attested and proved, the story, in brief, is that the disease originated in a farmhouse in which lived a peasant who had suffered from an attack of typhoid fever after returning from a visit to a distant point. About two months afterward typhoid fever appeared in all the houses in the village, with but six exceptions. These six houses were supplied through private wells, while otherwise the houses in town were supplied with water from a spring at the foot of a hill on which lived the peasant first attacked with the disease. The excreta from this man thrown upon the ground and contaminating the source of supply, were abundantly proved to have been the cause of the Lausanne epidemic of 1872. The town of Plymouth experienced an epidemic of typhoid fever during the year 1885. This epidemic was also proved, by incontestable evidence, to have been caused by an isolated case of typhoid fever in an isolated house in which lived a man whose discharges had been thrown near the source of origin of a stream of water supplying that city."

The remainder of Dr. Craig's paper is taken up with a description of the conditions prevailing in Albany with regard to typhoid fever before the institution of a filtration system, details concerning the installations of methods of filtering, and the great decrease in the typhoid fever rate in Albany in consequence of the adoption of filtration. Filtering drinking water was initiated in Albany in 1899. An average of 285 cases of typhoid fever per year for the years 1890, 1891, 1892, and an average of 489 cases a year for the four years preceding the introduction of filtered water falls to an average of 109 reported cases for the four years following such introduction. These figures would seem to prove in a most conclusive manner the good results proceeding from the purification of a drinking water supply by filtration, and particularly by sand filtration.

The effectiveness of filtration in purifying water on a large scale has been demonstrated times without number, and in Germany and in Great Britain, in most of the cities of which countries this system is followed, typhoid fever has so decreased as to warrant the belief that a general extension of the methods would end in the extermination of the disease. The MEDICAL RECORD has preached in and out of season the gospel of a pure water supply, but the municipalities of American cities have exhibited a curious apathy and a somewhat complacent disregard of all warnings and pleadings on the subject. It is nothing short of a municipal disgrace that, in the immensely rich, large centers of population of the United States, such a state of affairs with regard to the water supply should exist as has existed in Philadelphia since its foundation. But Philadelphia is by no means the only sinner in this respect. It is an uncommon circumstance for an American city to have a well protected water supply, while those in which the water supply is a constant source of danger, are too numerous to mention. In order to alter this state of affairs, the medical journals should neglect no opportunity of ventilating the matter, and of endeavoring to educate the public to a sense of the risks which a contaminated water supply entails. If the municipal conscience is too callous to be pricked, at least something may be done by appealing to the people's

fears. When the community becomes convinced that the lives and health of the population are endangered by a continuance of the present slipshod methods of supplying water, then will there be a universal demand for the institution of a proper system, and with this demand the municipal authorities will be compelled to comply.

PREVENTION OF MEASLES.

Measles is so common an affection with children that it is too frequently regarded as of little account. Parents look upon it as a disease which is certain to occur sooner or later, and are, perhaps, apt to think it is better that it should happen in quite early life and thus be done with, than that the disease should attack children of a more advanced age. The fact does not seem to be taken into consideration that measles is much more deadly among very young children than with those who are older and consequently better able to resist its injurious effects. At a meeting of the British Society of Medical Officers of Health, Dr. J. Howard-Jones read a paper on the control of measles. In the course of his remarks the writer said that in spite of 13,000 deaths occurring annually from measles in England and Wales no concerted action had been taken to check its spread. In Dr. Theodore Thompson's report to the local Government Board, the statements were made that from 90 to 95 per cent. of the deaths from measles were of children under five years of age, that the greatest fatality was during the second year of life, but that the incidence of the disease was heaviest in the third, fourth, and fifth years. "It would thus be understood," said Dr. Jones, "why it was that in a number of schools examined by Dr. J. Ker, medical officer to the London School Board, 75 per cent. of the children over five years old had already had the disease. It was therefore clear that the schools being the centres from which every epidemic spread and the great majority of the cases, with practically the whole of the deaths, being of children under five years, the attendance of such infants was directly responsible for the greater number of deaths. Their exclusion might not reduce the total amount of measles, since the infectivity of the disease was such that sooner or later nearly everyone contracted it, but it would by delaying the age of exposure and attack probably lengthen the intervals between epidemics and reduce the mortality."

In the case of measles a rapid and accurate diagnosis is an essential point, as the disease is most infectious in the prodromal stages. This, however, is most difficult. Dr. Koplik of New York pointed out some few years ago, that a correct diagnosis could almost invariably be made by noticing the presence or absence of what are known as "Koplik's spots." With reference to these Koplik says in his writings, "scant attention has been given to the most important elements of the eruption as it appears on the mucous membrane of the inside of the cheeks and on that of the lips. A thorough understanding of the eruption on the buccal mucous membrane will aid in separating an invading measles from a mass of eruptions resembling measles which appear on the skin in infancy and childhood Any positive sign of the invasion of any infectious or contagious disease is a step to proper isolation and prophylactic hygiene."

The points therefore which must be borne in mind in order to control the spread of measles are, that on account of its great infectivity in the early stages a prompt diagnosis is necessary, after which strict isolation of those infected should be enforced. A person with measles should be separated from those who are unprotected, in a room into which only the attendants should be allowed to enter. Isolation must be maintained until all symptoms have subsided.

Pulmonary Lesions Produced by the Bacillus of Hemorrhagic Septicæmia of Carabaos.

Dr. Paul G. Wooley, in Bulletin No. 12, published by the Bureau of Government Laboratories, Department of the Interior, writes on the findings with regard to the above subject in the biological laboratory at Manila. The lesions caused by the bacillus of hemorrhagic septicæmia in cattle are legion. Subcutaneous and lymphatic suppurations, gastrointestinal ulcerations and hemorrhages, widespread subcutaneous and subserous œdemas, pathologic joint conditions, and varying types of pulmonary changes are frequently seen, sometimes alone, but usually accompanied by ecchymoses. During the recent epidemic of hemorrhagic septicæmia which prevailed amongst the Government carabaos, Dr. Wooley and his coworkers have had opportunities to study many of these.

Among the animals which died of the infection, the report states that there was one in whose lungs were lesions so like those of contagious peripneumonia, that the investigators were at some loss to make a positive diagnosis until careful pathological and bacteriological examinations had been made. "The remarkable lesions were found in the thoracic cavity. When this was opened a quantity of pale, clear amber fluid gushed out. In the residual liquid in the pleural cavities were some fibrinous shreds. The pleural surfaces were, for the most part, covered with a well-marked fibrinous exudate which could readily be peeled off, leaving a reddened, congested, roughened surface. The pleura itself was thickened and œdematous. . . . The lungs were not collapsed, but contained air only in the anterior and apical portions, and in all respects, from both a pathological and bacteriological standpoint, the case exhibited all the signs of a purely infectious pleuropneumonia, and not one of the contagious type."

All three cases cited by Dr. Wooley were examples of the invasion of the lungs by the bacillus of hemorrhagic septicæmia.

"The facts," says the author, "in the clinical history of the first case seem to support Theobald Smith's theory of the etiology of the disease. The ocean trip, a rough passage, rough handling, all would tend to produce the primary bronchopneumonia and emphysema upon which the later stages follow. In this case the bronchopneumonia was perhaps the first stage of the disease. The presence of a very infectious disease in the same herd would account for the presence of the causative organism in the lungs of the infected animal. But even without the bacilli of hemorrhagic septicæmia in other animals, the organisms might have invaded the weakened animal from the upper respiratory tract in which they might have been present, and probably were, if the same conditions hold here as in the cattle which Moore examined. There is, too, a very good reason for the presence of these organisms in cattle here, if, as has been proved in other places, they are present in water. The health of the carabao, or water buffalo, de-

pends to a great extent upon the daily bath, which is usually taken in a wallow, in the thick mud of which the animals immerse or imbed themselves until only the ears, eyes, nose, and horns are visible. Frequently the whole head disappears from sight. Habits of this sort offer every inducement for such organisms as are present to enter the animal. However, we have not been able to demonstrate the bacillus of hemorrhagic septicæmia in the water or soil."

Indications and Contraindications of the Seaside Cure.

Dr. Alfred Gubb of Mustapha Superieur, Algiers, writes, in the *Medical Press* of August 3, regarding the seaside cure. He thinks that the seaside treatment may be advised in respect to the following categories of patients: anæmic patients with slowed nutrition, convalescents from febrile diseases, sufferers from malaria, patients of lymphatic temperament, the strumous, and in certain forms of neurasthenia with imperfect nutrition. The treatment is also suitable for rickety subjects, and in many osseous affections. Cases of chronic tuberculous adenitis with low nutrition will often be benefited by residence at the seaside.

Persons predisposed to pulmonary tuberculosis, whose nutritive changes are unduly active, should be kept at a distance from the sea. According to Robin, the great majority of the tuberculous derive no benefit from the seaside. Rheumatic subjects, with acute or subacute attacks, usually find their state to be aggravated by residence close to the sea, and the same may be said of arthritics subject to neuralgic attacks. Arthritics, whose nutrition is merely slowed; the subjects of arteriosclerosis without grave complications; the obese by nutritional slowing down; and the gouty and hyposthenic dyspeptic may derive marked benefit from the seaside. Certain phosphaturic neurasthenics also derive benefit therefrom, but the pure neurasthenic will, as a rule, do better in a sedative climate. Lastly, hysterical subjects are often worse near the sea, or feel so, but they need not, on that account, be sent elsewhere.

The indications for sea baths, according to Dr. Gubb, are in the case of the rickety, the lymphatic, the strumous, the subjects of osseous and glandular tuberculosis, in anæmia with slowed nutrition, in obesity by defective metabolism, in those predisposed to gout, in chronic autointoxication, in hyposthenic dyspepsia, in convalescence after febrile diseases, and in diabetics when nutrition has begun to give way.

A Fatal Infection by a Hitherto Undescribed Chromogenic Bacterium.

Bulletin 13, published by the Bureau of Government Laboratories, contains an account of the above by Dr. Maximilian Herzog of the Biological Laboratory, Manila. The observations recorded in the paper refer to a case of human infection by a hitherto undescribed bacterium, which is evidently not very pathogenic under ordinary conditions and probably is, as a rule, a harmless saprophyte, but which, under circumstances especially favorable, may become parasitic and may lead to a fatal issue.

A Filipino, forty years of age, died rather suddenly in hospital, and was sent to the morgue at San Lazaro. The suspected cause of death was plague, there being an open wound on the right leg, and a marked swelling of the inguinal glands of the right side. Among other post-mortem findings were these: Three of the inguinal glands of the right side were found to be markedly hypertrophic. On the left side they were slightly enlarged. The markedly hypertrophic glands of the right side were quite firm and rather pale. The cervical glands were slightly enlarged and very moderately congested. Smears from the organs showed a small number of what appeared to be small diplococci or diplobacilli. No organisms showing the characteristic morphology and staining properties of the plague bacillus were found.

When the bacillus was isolated its morphology was as follows: Short bacilli with rounded ends, varying much in size. The organism presents itself as a diplobacillus. It does not form long chains, even groups of four in a chain being but rarely seen. Spore formation is not observed. When properly stained, the organism somewhat, though rather remotely, resembles the short type of the pseudodiphtheria bacillus. A certain resemblance also exists between it and the bacillus of plague, though the similarity is not great. The name "Bacillus aureus fœtidus," selected for this microorganism, emphasizes two of its most prominent characters, its chromogenic and malodorous properties. Conclusions arrived at by Dr. Herzog were as follows: Experiments showed that the bacillus was not a highly pathogenic microorganism, because single inoculations of moderate doses brought about only a very slight reaction in the animals experimented upon.

It is very probable that *Bacillus aureus fœtidus* is ordinarily a saprophyte. In the case reported it may simply have lived for some time in the necrotic tissues of a neglected ulcer, and may have slowly become modified in these environments until it finally gained entrance into the tissues of the patient. From the lymphatic system it entered the blood current, reached the liver and kidneys, and led to subacute and somewhat chronic interstitial fibroid process and parenchymatous degeneration.

Suicide in Chicago.

In August there were forty-two suicides in Chicago, according to the Chicago *Record-Herald* of September 3. This is ten more than in the corresponding month last year, and four more than the monthly average last year. In most countries the proportion of suicides is largest in the hot summer weather, but recent Chicago suicides do not indicate a similar tendency there. The large number of suicides in the exceptionally cool August of this year is itself in conflict with the generalten dency.

The method by which suicide was committed last month was gas asphyxiation in fourteen cases, carbolic acid in eleven, drowning in seven, hanging in three, and shooting in three, leaving only four cases for sundry less usual methods. The *Record-Herald* remarks: "This aspect of suicide is grewsome, but nevertheless, it is important and deserves consideration because of the efforts that are from time to time made to take away from would-be self-murderers their easy opportunities for attaining their end. A reference to Mulhall's Dictionary of Statistics shows that in nearly all European countries hanging and drowning have been chosen by more than two-thirds of the suicides. In Chicago to-day these two forms of death are comparatively rare. They were chosen, it is true, by almost one-quarter of last month's suicides, but in 1903 they were chosen in less than one-seventh of the total number of cases. On the other hand, carbolic acid has for some time been the main resort of Chicago's suicides, and it furnished a means of death to more than one-third of the total last year. Now, however, it would

seem that it is being replaced by gas asphyxiation, which was made use of in fourteen cases in August as against eleven in which carbolic acid was taken. From less than one-ninth of the cases last year gas asphyxiation has sprung forward till it is employed in one-third of the cases in August."

As the writer in the Chicago paper says, it is possible to make the sale of carbolic acid in concentrated form difficult to any but physicians or persons provided with a physician's prescription, but if ordinary illuminating gas is the agency henceforth to be favored, it would seem to be impossible to devise any effectual method of preventing its use. Even in buildings where this has been replaced by electricity for lighting purposes, it is usually piped to the rooms for use in heating or cooking

News of the Week.

A Reception in Honor of Our Medical Guests.—A reception will be tendered by the New York Academy of Medicine on Thursday evening, October 6, at half-past nine o'clock, to the many distinguished medical men now in this country, most of whom have been in attendance at the International Congress of Arts and Science in St. Louis.

Dr. Chapin's Jubilee.—Dr. John B. Chapin, superintendent of the Pennsylvania Hospital for the Insane in Philadelphia, who has been for fifty years engaged in work in behalf of the insane, is to be entertained at a dinner given in his honor in October. At the same time his medical friends will have his portrait painted. He was appointed assistant physician to the New York State Lunatic Asylum, Utica, in 1854. Afterward he became connected with the late Dr. George Cook in the conduct of Brigham Hall, Canandaigua, N. Y., and then, first as one of the building commissioners, and subsequently as physician and superintendent, with the Willard Asylum for the Chronic Insane.

Vaccination Controversies in California.—More than two hundred children were refused admission to the public schools of Berkeley, Cal., on account of their not having been vaccinated. Among those who involuntarily submitted to vaccination, one little girl contracted tetanus and died. Now the antivaccinationists are up in arms, and suit has been threatened against the "responsible parties." Fortunately, the physician who performed the vaccination was serving in an official capacity, and the responsibility for his act rests upon the State.

Death of Dr. Niels Finsen.—It is announced that Dr. Niels Finsen died in Copenhagen on September 24. He was the originator of the method of treating lupus and other affections of the skin by means of the violet and ultra-violet rays. He used first the sun's rays, but those are rare in Denmark, and he was forced to employ the electric light, which he found would give equally good results. He was greatly assisted in the extension of his work by Queen Alexandra of England, who provided a complete set of apparatus for one of the London hospitals and secured the introduction of the method in England. Finsen also advocated the employment of red light as a preventative of the pitting of smallpox. The Nobel prize was awarded him in 1903.

Quarantine Rules for Diphtheria.—The Iowa State Board of Health has issued the following rules relative to the quarantine limit after diphtheria: Quarantine shall be released in those houses in which diphtheria has been diagnosed when synchronous cultures taken from the noses and throats of all infected persons quarantined show two consecutive negative examinations, providing the regulations of the Board regarding disinfection and fumigation have first been complied with. Those who have been quarantined with diphtheria patients may be released from quarantine, when both nose and throat cultures on examination by a bacteriologist of the State Board of Health do not show the presence of diphtheria bacilli. In districts where it is not possible or desired to use the laboratory findings as a means of regulating quarantine, those suffering from diphtheria shall be quarantined for a period of not less than four weeks for initial symptoms when antitoxin is used, and five weeks when antitoxin is not used.

Medical Society of the County of New York.—At a meeting of this society on Monday, September 26, the following officers for the coming year were nominated: *President*, Dr. Henry S. Stearns; *Vice-Presidents*, Drs. F. M. Crandall and W. L. Carr; *Secretary*, Dr. J. V. D. Young; *Treasurer*, Dr. C. H. Richardson.

The Eastern Medical Society.—The first open meeting for the season of the Genitourinary Section of the Eastern Medical Society, will be held on Tuesday evening, October 4, at the society rooms, 151 Clinton Street, at 8 P. M. The paper of the evening will be "Ureteral Catheterization—with Special Reference to the Treatment of Pyelonephritis Catarrhalis," by Dr, Winfield Ayres. The paper will be discussed by Drs. W. G. Pulley, Follen Cabot, Frederic Bierhoff, Ferd. C. Valentine, and possibly others. Cases will also be presented.

Hertzstein Lectures at the University of California.—It is announced that the first series of the Hertzstein lectures will be delivered in October, by Dr. A. E. Taylor, Professor of Pathology. The lectures have been made possible through the generosity of Dr. M. Hertzstein, of San Francisco, who fully equipped the physiological laboratory and endowed the lectureship for the discussion of special problems in scientific medicine. Professor Taylor's subject will be "Ferments and Fermentations." The lectures will be delivered on Tuesdays and Thursdays and will be open to the public, particularly to medical students and physicians.

Medical Society of Virginia.—The thirty-fifth annual meeting of this society will be held at Richmond, October 18-21, under the presidency of Dr. Joseph A. Gale of Roanoke. On Wednesday morning, October 19, there will be a discussion on serum therapy, the following papers on this subject being announced 1. "Theories of Serum Therapy," by Dr. Charles R. Grandy, Norfolk; 2. "Sera for Diphtheria, Tetanus, Streptococcic Infections, the Plague, and Pneumonia,' by Dr. J. S. Davis, University Station, Charlottesville; 3. "Other Sera, Including Those for Tuberculosis, Dysentery, Typhoid Cholera, Snake-Venom, and Veterinary Diseases," by Dr. Ennion G. Williams, Richmond; 4. "Organotherapy," by Dr. Lewis G. Pedigo, Leatherwood. The "Annual Address to the Public and Profession" will be delivered by Dr. William S. Gordon of Richmond on Tuesday evening, October 18, and this will be followed by the "Address of the President." The corresponding secretary of the Society is Dr. John F. Winn of Richmond.

An Old Code Medical Association.—In a letter to the *Lancet-Clinic*, Dr. J. R. Allen announces the formation of a new national medical society (the membership in which is at present confined to Covington, Ky.) by some physicians who "refuse to be reconstructed on the present plan of the American Medical Association." They purpose to reaffirm the code of ethics as adopted by the American Medical Association in 1847, unamended and unrevised,

and agree to be guided by this code and the Hippocratic oath in their daily conduct. They charge that "the action of the American Medical Association in allowing the affiliation of all legally qualified physicians was prompted by the commercialism of specialists, and is the direct result of their greed; that it was done to enlarge the consultation field; that it is a step toward making a trade of what we have fondly looked upon as a profession; that it is a concession of honor, a confession that the regular profession has been wrong for over half a century; that it is the sale of a birthright for a mess of pottage." Further, that "specialists began this degradation in the new code movement of 1882, and that it has culminated in the humiliating position in which the regular profession is now placed, the present organization compelling the fellowship of all legally qualified physicians, with membership in the American Medical Association used as a means of compulsion, as a whip." We understand that the new organization looks for a recruit from New York State.

Extermination of Mosquitos.—The New Jersey State Commission on Mosquito Extermination recently held a meeting in Newark to receive reports of work done during the past summer. Prof. John B. Smith, state entomologist reported that in the two large operations carried on during the past season absolute success had been obtained. The first operation was in the region about the mouth of the Shrewsbury River and the government reservation on Sandy Hook. Beginning early in the season, more than 250,000 feet of ditching was cut through the salt meadows, and throughout the region drained by these ditches not one mosquito had been bred this summer. The evidence of the good results of this operation was so marked that the North Long Branch authorities were anxious to join in the work and complete the drainage of the mosquito breeding places in that section. The second big operation, the salt meadows contiguous to Newark, Prof. Smith declared, would result in the complete suppression of mosquito breeding in that section.

A Gift to McGill University.—At the opening exercises in connection with the medical department of McGill University, Montreal, Dr. Roddeck announced that Lord Strathcona has made a donation of $50,000 to the endowment fund of McGill Medical College. This magnificent contribution is not the first from Lord Strathcona, who has always been a warm friend of McGill.

Consolidation of Medical Journals.—Announcement is made of the consolidation of *Southern Medicine*, published in Savannah, and *Gaillard's Medical Journal*, published in New York, the united journals to be published in Savannah under the editorial management of Dr. William Edwards Fitch. In announcing the change, the editor says that "In 1897 the present editor of *Southern Medicine* established the *Georgia Journal of Medicine and Surgery*. On the first of January, 1904, *Southern Medicine* was thought to be a more appropriate name. *Gaillard's Medical Journal* was established at Richmond, Va., in 1866, by Dr. E. C. Gaillard, a Charlestonian, and a graduate, in 1854, of the State Medical College of South Carolina. Dr. Gaillard was a prominent surgeon in the Confederacy, and *Gaillard's Medical Journal* has always been considered a Southern journal though for many years past it has been published in New York City."

An International Congress of Military Surgeons will be held at St. Louis, October 10-15. The opening session will be on Monday afternoon, October 10, at 2 o clock; the other sessions will convene at 9 A. M. on the successive days of the meeting.

Dr. William A. Edwards, for many years a prominent surgeon of San Diego and Coronado, Cal., and well known as a medical writer, has recently gone to Los Angeles, where he assumes the chair of pediatrics in the medical department of the University of Southern California.

Dr. S. Henry Dessau has resigned from the faculty of the New York School of Clinical Medicine.

Losses of Russia in the War.—A despatch from St. Petersburg says that the General Staff issued, on September 22, a detailed list of the casualties of the Russian army at Liaoyang. It gives the following figures: Men killed, 1,810; wounded, 10,811; left on the field, 1,212. Officers killed, 54; wounded, 252; left on the field, 5. Two Generals were killed and three were wounded.

An Italian Hospital in New Orleans.—A donation of a quarter of a million dollars has been made by Mr. Salvatore Pizzati, a resident of New Orleans, to found an Italian hospital in that city.

Hospital for Panama Convalescents.—It is announced that a hospital will be established at New Orleans for the reception of officials who will have been invalided home from the Isthmus during the construction of the canal.

Testing the Moore Theory.—The Illinois State Board of Health has instituted a number of experiments to determine the correctness of the assertion that water containing typhoid bacilli will be sterilized by standing for a few hours in a copper vessel.

Pneumonia Increasing in Chicago.—The deaths from this disease in Chicago, for the week ended September 17, were thirty-four, an increase of fifteen, or nearly 80 per cent., over the mortality of the previous week from this cause.

Crime and Cocaine.—There has been a large number of crimes committed lately by the colored population of Cincinnati, and Chief of Police Millikin attributes it to the large increase in the cocaine habit, especially among these people. It is estimated that 250 ounces of the drug are sold to them each month.

The French Surgical Association.—The seventeenth annual meeting of this association will be held in Paris in the hall of the Faculté de Médecine, October 17-22, under the presidency of Dr. S. Pozzi. Three subjects are announced for discussion, as follows 1. "Surgical Treatment of Cirrhosis of the Liver," opened by Dr. Monprofit of Angers; 2. "Diagnostic Value of Blood Examinations in Surgery," opened by Dr. Tuffier of Paris; 3. "Traumatic Separation of the Epiphyses," by Dr. Kirmisson of Paris. The secretary-general is Dr. Walther, 21, Boulevard Haussmann, Paris.

Cholera at Port Arthur.—A despatch to *The Sun* says that the Russian naval officers at Kiaochau have received official advices of an outbreak of cholera in Port Arthur. Only a few cases had developed up to September 19, but grave fears of an epidemic were entertained.

American Academy of Ophthalmology and Otolaryngology.—At the Denver meeting of this society, held on August 24, 25, and 26, 1904, the following officers were elected: *President*, Dr. H. W. Loeb of St. Louis; *Vice-Presidents*, Drs. D. T. Vail of Cincinnati, Robt. Levy of Denver, and Eugene Smith of Detroit; *Secretary*, Dr. Geo. F. Suker of Akron, Ohio; *Treasurer*, Dr. Otto J. Stein of Chicago; *Council:* Drs. H. W. Loeb, Edw. Jackson,

W. L. Ballenger, Casey A. Wood, and J. M. Ray of Louisville.

The Cost of a Paraffin Nose.—A woman in this town was kicked in the face by a horse some years ago and lost the bridge of her nose. When paraffin prosthesis came into vogue she thought she saw in it a means of recovering a measure of the good looks she had lost, and accordingly submitted herself to the manipulations of a physician. She paid for the operation and subsequent treatment $246, but not being satisfied with the cosmetic results, recently sued the surgeon to recover this amount. The judge, however, after an inspection of the before and after photographs, dismissed the suit, holding that the surgeon did improve the plaintiff's appearance so far as nature would permit.

Obituary Notes.—Dr. George S. Conant of this city, died suddenly on September 23, at the age of fifty-one years. He was born in Troy and was graduated from the Bellevue Hospital Medical School in the class of 1877. He had been a sufferer for several years from diabetes. He willed his brain to Cornell University.

Dr. John J. Mackey of Brooklyn, died at his home in Bergen Beach, on September 24, after a prolonged illness. He was born in Dublin, Ireland, and when sixteen years old he entered the Medical School of the Dublin Catholic University, coming to this country a few years later with his parents. He was graduated from the Bellevue Hospital Medical College, in the class of 1882.

Dr. Juan N. Navarro, consul-general for Mexico in this city, whose death from apoplexy occurred on September 24, was for nearly twenty years of his life, a practising physician. He was born in Morelia, Michoacan Mexico in 1823, and was graduated with honors from the School of Medicine in the City of Mexico, and immediately began the practice of medicine. He entered the ranks of the Mexican Army at the outbreak of the war between Mexico and the United States and soon rose to the rank of colonel. After the war he returned to the practice of his profession, but later was elected to the Mexican Senate. Throughout the war with Maximilian he was Surgeon-General of the Mexican Army. After its close, he returned again to practice, but was soon appointed Consul-General at this city. He took up his duties here in 1863, and had lived in New York continuously ever since.

Dr. James G. Hyndman of Cincinnati, died at the Good Samaritan Hospital in that city on Sunday, September 18, after an illness of ten days. He was born in 1853, obtained his Academic education in the old Woodward High School in Cincinnati, and was graduated from the Medical College of Ohio before he became of age. He then served as interne in the Cincinnati Hospital and later became connected with the Medical College where, for seventeen years, he has been secretary and professor of Laryngology.

Dr. Herman Schafer, formerly residing at San Diego, died September 1, at Monrovia, Cal. He received his medical degree from the Long Island College Hospital, in 1866.

Dr. Josephine Briggs, a native of the State of New York, died in Pasadena, Cal., on September 8, at the age of fifty-six years. For many years previous to their coming to the Pacific coast, she and her husband Dr. Solon Briggs, engaged in practice in New York City. Mrs. Briggs had been totally blind for the past eight years, yet endeared herself to a large circle of acquaintances by her charming personality, the brilliancy of her intellect and her continued activity in literary and religious undertakings.

Professor Wassermann's Lecture on Immunity.

Professor A. Wassermann of Berlin delivered an address on "Several New Points Concerning the Theory and Practice of Immunity" before the New York Pathological Society, September 28, 1904.

The first condition to be fulfilled by a substance which is to serve for immunizing against any toxin, he said, is that it must form a firm union with the cellular elements of the organism. Thus, we cannot immunize against strychnine because this poison does not form a firm chemical union with the cell, but may be readily dissolved out of the tissues of the poisoned animal. This is not so with a bacterial poison, *e. g.* tetanus toxin, which forms a firm union with the nerve cells which it affects. According to Ehrlich, the specific immunizing substances, which are formed in the animal body and are contained in the therapeutic serums, are simply those portions of the cells which have a specially marked affinity for the specific toxin which it is desired to neutralize. The parts of the system which receive and are acted upon by a specific toxin are called "receptors"—those portions of a toxin which carry the poison to the receptors are called "haptophores" and those portions of a toxin which represent the actual poison are the "toxophores." A "toxoid" is an attenuated toxin which has still haptophores, but no toxophores. It may be compared to a snake with its poison glands removed.

When a toxin is injected it unites with the specific receptors which possess special affinity for it. Then the law of over-compensation, declared by Weigert, is brought into play, and there is a great over-production of receptors. When this has reached a sufficient degree, the receptors are thrown off as ballast, and circulate in the blood as "antibodies." Hence the specific sera are nothing but "receptors."

The process of immunization therefore takes place in three stages: (1) The union of toxin with receptor, (2) the over-production of receptors, and (3) the elimination of the receptors in the blood. To prove the occurrence of the first two of these stages has been a matter of some difficulty in the past, but the speaker said he had succeeded in doing this recently, with the aid of his assistants at the Berlin Institute for Infectious Diseases.

He injected an old attenuated tetanus toxin which he had kept since 1896 into guinea pigs, and found it to be so weak that no tetanus resulted. This toxin was thus really a "toxoid," for it did not possess any "toxophores" or real poisons, but merely the "haptophores" or poison-carriers. Of this tetanus toxoid he injected $\frac{1}{2}$ c.c. into guinea pigs. He then injected virulent tetanus toxin fifteen minutes after injecting the immunizing dose into these animals, and found that a larger amount of the toxin was needed to kill them than to kill the control animals. This was because a portion of the toxins had already been tied to the receptors. When the virulent toxin was injected three hours after the weak toxin, the animals required less of the former to kill them than those of the first series, in fact less than normal animals. This meant that the second stage of immunization, the increase of receptors, had set in when the virulent tetanus toxin was injected. The third stage—elimination of receptors—is not a function of the haptophores. For this toxophores must be present.

The question as to the relation of antitoxins to toxins has been widely discussed and studied. Arrhenius and others tried to apply to it the laws of pure physics and mathematics, but the speaker did

not think that these could be successfully made use of in this connection in a living being. He was able to show by experiments that antitoxin first forms a loose chemical combination with toxin, and then gradually enters into a closer and firmer union with the latter. It is well known that tetanus toxin is absorbed only through the nervous system, *i. e.* it is neurotropic, while tetanus antitoxin is absorbed through the blood channels. He injected a mixture of toxin and antitoxin into guinea-pigs, and no tetanus followed. Then he injected the same mixture into guinea-pigs after having injected a solution of adrenalin into the area attached (the hind leg). These animals did develop tetanus because the toxin went in by the nerve route, while the blood route was closed in virtue of the contraction of the capillaries by the action of the adrenalin, so that the antitoxin could not get in. The antitoxin was therefore in loose chemical combination with the toxin. But this took place only when the mixture in the bottle had been allowed to stand for a short time. When the mixture of toxin and antitoxin was allowed to stand over half an hour, the combination was firm, and the guinea-pigs did not develop tetanus in these conditions. The combination became firm within fifteen minutes if the mixture was warmed, or if there was an excess of antitoxin in it.

The practical applications of immunization, the speaker said, were, of course, of the greatest interest. One great difficulty encountered hitherto in serum therapy was that some serums immunized only against a certain "race" or species of germs. This was because the bacterial cellbody was composed of different elements which are called "partial groups." Each of these elements has its corresponding receptor in the serum. Now various races of germs of the same species have different partial groups of elements in their bodies—just as each variety of oak is built slightly differently, and and yet all are of the same species. Some receptors are common to all, but some are present only in a certain race of the same variety of germs. The conclusion is, that, in order to obtain a serum of general utility, we must use colonies of a large number of races of germs—as, for example, diphtheria bacilli taken from many different children. Very good results have already been attained in the treatment of swine plague with this method.

About a year and a half ago the speaker prepared a new diphtheria serum on these principles. The old serum is only antitoxic, and does not act upon the bacilli proper. This new serum is also agglutinating and directly affects the germs. It is prepared from cultures of many "races" of germs, and, therefore, is called "multipartial." One part in 5,000 agglutinates diphtheria bacilli.

The speaker, and also Martin of Paris, had dried this serum, powdered it, mixed it with sugar of milk, and made tablets of it, which, when dissolved in the mouth of diphtheria convalescents who had still Loeffler bacilli in the throat, agglutinated these germs. Then a gargle was given, and the germs were quickly removed, while ordinarily it took weeks for them to disappear. The action of the new serum tablets was mechanical, and also stimulating to phagocytosis. The white cells are attracted and swallow large numbers of the bacilli, thus removing them from the infected spot. The new method is also used in nasal diphtheria in children, in the form of a powder blown into the nose, an alkaline wash being subsequently used to remove the germs. Experiments with this new serum in Berlin and Paris, Dr. Wassermann said, had given very favorable results.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE COMING SESSION—PROFESSIONAL PROSPECTS—LUNACY QUESTION—THE "NEW BODY," ITS NAME—PIROPLASMA OR TRYPANOSOMA?—HOSPITAL ABUSE—SANITARY INSPECTORS IN CONFERENCE.

London, September 9, 1904.

We are now in what may be called the dead season, so far as medical topics are considered, for a great proportion of men are on their holidays. But the winter session will soon be upon us, and already our journals are issuing their so-called students' numbers, which, with a few words of advice, contain for the most part the official regulations of our too numerous corporations and schools—a series of advertisements, in fact, of these institutions. After the manner of introductory addresses, they also devote a few lines to the glorification of the profession, and one of them this year has circulated to the general press a statement of its pecuniary prospects, saying that the young qualified practitioner "should be able to earn from £400 to £500 a year." Alas for the hope! Hundreds of qualified men are only able to scrape a bare existence by accepting the lowest prices and competition is constantly increasing. Even among the higher walks there are many able young physicians and surgeons who have never earned as much, and are plodding on steadily in hopes that with hard work distinction and some more solid remuneration will come to them.

On Wednesday the fifty-eighth annual report of the Commissioners in Lunacy was issued, and as there has of late years been so much discussion as to the alleged increase of lunacy, some of the statistics may interest you. At first sight the figures seem to support the opinion that there has been considerable increase. On January 1 there were 117,199 persons in England and Wales certified to be insane, being 3,235 in excess of the number on the same date last year. The average annual increase for the previous ten years was 2,513. But, of course, the total population, of which the insane form a fraction, has also been increasing. The returns show that the numbers of insane under care have for some years been increasing at a greater ratio than the growth of the population, but this increase is practically confined to the "pauper class." The rate of increase in the decade 1891 to 1901 (last census year) of the population was 12.2 per cent. of the insane, 24.4. But the ratio of insane to population in that period was only 10.9 per cent. The figures giving the assigned causes of insanity do not materially differ from those of previous reports, and they are only approximately true. Moreover, in any one case more than a single antecedent condition, predisposing or exciting, may be present. A "previous attack" was recorded in 16.1 per cent. of male admissions and 22.6 of females; heredity was noted in 18.6 per cent. males and 24.4 per cent. females. The chief physical cause was "alcoholic" intemperance; 22.8 per cent. of males and 9.5 females. This cause is more prominent among the pauper class, while the rates for private patients were higher for "moral causes," especially those involving anxiety and worry, than for the paupers.

It is refreshing to find that the commissioners renew their protest against the tendency to undue increase in the size of asylums for the insane poor. Its advocates try to justify it on the ground of convenience and economy, but many persons, especially those who feel the increasing burden of the rates, hold that extravagance is a more appropriate word for the lavish expenditure on huge buildings which has of late prevailed. The commissioners favor asylums of simpler construction for the aged and harmless, who are now removed in increasing numbers from their homes and workhouses into asylums built and fitted for acute cases. They think such asylums could be built and furnished less expensively, and well they may; for it is monstrous to hold that these patients require the same medical and nursing care and as luxurious apartments as rich patients can obtain in private institutions. To take a pauper from the workhouse and put him in a palatial hotel at the expense of the struggling ratepayer is an absurdity which would only be committed by boards, the members of which do not have to "pay the piper." The weekly cost of the maintenance of pauper lunatics is reported to be increasing.

Trypanosoma or piroplasma? which is it? It has generally been called the Leishman-Donovan body. Major Leishman's description at Oxford will be fresh in your memory. He found the parasite in 1900 and published his first description in 1903. Major Donovan found it a little later and sent specimens to Laveran and Mesnil, who named it *piroplasma Donovani*. Colonel Bruce would call it Leishman's body parasite, and others desiring to do justice to all offer the cumbersome name, "The Cunning-

ham-Leishman-Donovan body." Now Captain Rogers says he has seen it develop into trypanosoma. If this observation be confirmed, the name piroplasma must be rejected. I think I will follow some observers and be content while the experts settle the matter, to call it "the new body."

An official of the London Hospital in the course of an interview respecting abuses brought before the committee by the local medical societies, remarked that "it is very difficult to gather accurate particulars of every case when about four hundred patients pass through the receiving wards daily." He did not seem to think it possible that the fact of the reception of four hundred out-patients a day is important evidence against the management. He admitted that the hospital is often abused, many persons coming for treatment who could well afford to go to general practitioners. He even quoted glaring instance that had been mentioned by the medical society, and said the chairman of the hospital had suggested that the local doctors should make it their business to walk round the receiving wards daily, note the cases, and report to the secretary any person they recognized as not in need of charity, on receipt of which report the secretary would investigate it. Was there ever a more preposterous proposal! The half-ruined doctors are to spend their time in parading among the four hundred persons attending the out-patient department and report to the secretary the abuses they see. No greater indication of a determination to continue the competition is required—and this competition is pauperizing the population as well as the doctors.

The sanitary inspectors are holding a congress this week at Bournemouth, where they have been warmly received by the Mayor and corporation and accorded the use of the Municipal Building for the occasion. Papers on various subjects connected with the duties and responsibilities of a sanitary inspectors have been submitted to discussion and some on wider subjects, such as aspects of the Hygiene of a Health Resort—very appropriate to Bournemouth; factory laws and local authorities; the inspector's responsibility for prosecutions and the Food and Drugs Acts. The chairman of the Central Committee gave an address on Thursday, in which he pronounced the present rate of infant mortality a blot on our civilization and said inspectors only wanted to do their duty fearlessly and benefit everyone around them. A reception was given in the winter gardens by the Mayor and Mayoress, and Sir J. Crichton-Browne, M.D., delivered an address to the members of the association.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Sept. 22, 1904.

Exploratory Laparotomy in Cachectic Subjects.—Daniel Fiske Jones believes that ether is the most satisfactory anæsthetic in cases of exploratory laparatomy. If the patient is not strong enough to stand ether narcosis, operation should not be done. The incision should be in the median line, unless strongly contraindicated, and its length should be from two to two and a half inches as a rule. The surgeon must have clearly in mind what is operable and what is not. A positive diagnosis, however, in every case after opening the abdomen, is impossible. The surgeon should be the only one to make the diagnosis and the only one to judge of the advisability of proceeding. Gauze should not be used for walling off if it can be possibly avoided, as it increases shock and makes convalescence more painful. The most rapid method of suture is the simple through and through method with silkworm gut. But a safer method is to place the silkworm gut sutures and then put in a row of interrupted silk sutures, including the sheath of the rectus, the rectus, and peritoneum, after which the silkworm-gut sutures are tied. The writer emphasizes the importance of rapidity in these operations. He declares that one can open the abdomen, make a diagnosis, and close the abdomen in ten minutes or less, as well as in half an hour.

After-treatment of Gastroenterostomy.—E. A Pease believes that it is well to begin feeding immediately after the cessation of the nausea or vomiting, gradually increasing the amount as rapidly as after an ordinary case of laparotomy. Milk and lime water, beef juice, veal tea, black coffee, brandy and water, and sometimes very dry champagne, are given in teaspoonfuls every half hour at first, and soon increased up to half ounces every hour. It is important to see that no unusual strain comes at the seat of operation, as would be caused by vomiting or flatus. To avoid the after vomiting, the author has the stomach washed out just before the ether is given, and he also gives a small dose of morphine, $\frac{1}{8}$ and atropine, $\frac{1}{100}$ subcutaneously. The excretion of mucus is is thus stopped for the time, and restlessness is calmed. Morphine is rarely given besides this dose, only on the evening of the operation, and then, if restlessness or pain demands it. The flatus should be dissipated. For this a rectal tube is placed in the rectum soon after recovery from ether, and if no gas comes, and there is distention, an enema of suds and glycerin is given. Calomel, $\frac{1}{10}$ grain, is given every hour, till one grain is given, beginning the evening of the operation. Nothing effervescing is given, until after forty-eight hours from the operation. If there is nausea and vomiting, tablets of cocaine, $\frac{1}{10}$ grain hourly often stop it. If due to bile, drainage of the gall-bladder is often successful. The patient should have the head and shoulders raised on a pillow or two to allow the contents of the stomach to drain into the intestine. This position also better allows the bile to flow naturally along the intestinal course instead of flowing back into the stomach.

Special Preparation of the Patient for Operations on the Stomach.—C. A. Porter states that although in emergencies, such as perforation or acute gastric hemorrhage, no previous preparation of the patient can be made; nevertheless, if possible, the rectum should be thoroughly emptied previous to or during anæsthesia, in order that subsequent enemata may be given. In operations of election, however, attempts may be made to improve the nutrition and anæmia, to empty the stomach, and to render it and the upper intestine as free from bacteria as possible, and to minimize shock. The writer believes that the value of rectal feeding has been overestimated. This does not apply to cases in which an ulcerated stomach must be rested, but to prolonged attempts to improve the nutrition previous to operation by nutritive enemata. It is a delicate question of judgment to decide as to the amount of preliminary treatment to be given in cases which have not received proper medical treatment, and in those in which there is pyloric obstruction and starvation. In cachectic cases, especially those of stasis, the organ should be cleansed for a week or ten days, by daily, or twice daily stomach lavage. Easily digested foods leaving small residue, may be given at short intervals. The fluid for washing the stomach is of secondary importance, and warm saline, bicarbonate of sodium, or boracic-acid solutions are among the best. The value of antiseptics is doubtful. Not more than a week, as a rule, should be given to this preliminary treatment. The amount of a rectal feeding should not, as a rule, exceed 8 to 10 ounces, three times in twenty-four hours. In exceptional cases of very marked cachexia, or malnutrition, besides the stomach and rectal feedings, the subcutaneous use of sterilized olive oil, and 10 per cent. glucose solution may be used. The weight gained may be rapidly lost, and at the first step backward, operation should be done. In cases of gastric stasis, the amount of urine is apt to be small, and for several days before operation the patient should have plenty of liquids. The following treatment may be suggested for rendering the operative tract as clean as possible: Gastric lavage, once or twice daily, until the fluid returns clean; careful attention to carious teeth and suppurating gums; free catharsis by salines when it is not contraindicated, and the administration of nothing but sterilized food and boiled water by the mouth. This last factor is open to some question. On the evening before operation, the stomach should be emptied and washed out, and no food should be given after this. The operation should be done in the morning. The value of washing out the stomach after anæsthesia has been induced, is difficult to estimate. Careful attention to the prevention of shock is most necessary in these cases, on account of the poor condition of the patient. The temperature of the room should be from 72° to 75°. The patient should be well wrapped. Anæsthesia should be as light as is compatible with the conditions present. All delay should be avoided. Morphine and atropine given half an hour before operation often produce a quieter anæsthesia.

Journal of the American Medical Association, Sept. 24, 1904.

Autochthonous Sinus Thrombosis of the Cerebral Dura.—William G. Spiller and Carl D Camp report three such cases which belong distinctly to that class of cases in which the thrombosis is due to a general bodily condition. An extensive review of the literature upon this subject follows.

Symptomatic Cure of Convulsive Tic Douloureux by Injections of Osmic Acid.—Joseph Rilus Eastman reports the case of a woman, seventy-one years old, who had a typical intense tic douloureaux involving the right side of the face. The first attack occurred twenty years ago, and the attacks gradually became more frequent and more severe, and practically all the remedies recommended had been tried without benefit. A two-per-cent. solution of osmic acid was injected into the supraorbital, infraorbital, and dental nerves. The manner of operating was precisely that practised by Dr. John B. Murphy. Ten drops of this solution were injected into each branch and two

or three drops were forced into the perineural fat of each foramina around the nerves. One week after the injections the symptoms abated and there has been no return of the pain since. An interesting feature of the case was the severe nephritis occasioned by the elimination of the acid.

A Case of Early Acute Pancreatitis without Hemorrhage.—H. H. Germain and H. A. Christian give the clinical narration of such a case which was of less than four days' duration from the onset of the first symptoms. The clinical history was a fairly characteristic one. All of the findings seem to point to an intense intoxication due to a pancreatic lesion which is described. The etiology is not clear. There is no indication of any entrance of bile into the organ. There is a duodenitis. Assuming this to be the primary lesion, extension may have taken place to the pancreas either by way of the pancreatic ducts or by direct extension, possible in the close connection existing between the duodenum and the head of the pancreas. This cannot be said to be a clear case of pancreatitis of bacterial etiology. The interest of the case lies in its short duration, the extent and character of the inflammatory lesion, the slight degree of the necrosis of the pancreas and fat tissue, and the absence of hemorrhagic lesion. Such a case strengthens the belief in the inflammatory nature of acute hemorrhagic pancreatitis.

X-ray Therapy in Leukæmia.—Joseph A. Capps and Joseph F. Smith make this preliminary report with special reference to lymphatic leukæmia, and their general conclusions are as follows: 1. The action of the *x*-ray in leukæmia seems to be of two kinds: (*a*) A local influence on the spleen and glands, characterized by an inflammatory reaction and later by a breaking down and disintegration of the gland tissue. (*b*) The formation of toxins which have an inhibitory action on the manufacture of leucocytes by the bone marrow. 2. In no recorded instance of either lymphatic or splenomyelogenic leukæmia has the spleen tumor entirely disappeared. 3. With the discontinuance of the *x*-ray, the disease, after varying periods, tends to reassert itself. 4. Death may take place when the glands and spleen are smallest, and when the white count is normal. 5. Acute cases seem to receive no benefit from the *x*-ray. 6. The chronic form of lymphatic leukæmia responds to the *x*-ray even more promptly than the splenomyelogenic type. In every instance the glands rapidly softened and dwindled to small proportions. 7. The *x*-ray holds the disease process in abeyance, but probably is not curative. Yet it is too soon to say that persistent treatment of an early case may not give permanent relief.

Medical News, September 24, 1904.

Bone and Cartilage in the Tonsil.—James E. Newcomb briefly reviews a number of cases of this nature which are reported in the literature, first giving the history of a patient who came under his care. The patient was a woman of about thirty years, who presented herself for treatment for frequent though slight sore throat. The faucial tonsils were moderately enlarged, and their removal was advised. The Mackenzie instrument was employed, and the right tonsil was removed with no complications. A few days later the left side was operated upon, and as the blade of the instrument was driven in, a hard substance was encountered. This tissue, however, was easily pierced. On examining the tissue that had been removed, a small tip of bone was discovered. On palpating the tonsillar stump, it was noted that the tip of bone had been removed from the styloid process. It was, therefore, a case of abnormal length and direction of the left styloid process. The writer declares that it is not possible to state just how common this anomaly is. For, although few instances are on record, the report of an unusual clinical case is apt to call forth reports of similar cases, so that what at first was considered very rare is found later to be quite common. According to the writer, there does not seem to be any special importance attached to this condition, unless the bony projection is long enough and the direction of the styloid process oblique enough to cause tonsillar irritation. The abnormality seems generally to be discovered accidentally. There is a more voluminous literature in relation to bony deposits scattered through the tonsils. Cartilage has also been found. The writer himself has removed tonsils which showed masses too large and too hard to be foci of connective tissue and which were probably cartilaginous, but this was not confirmed by microscopical examination. Wingrave found cartilage three times in examining two hundred tonsils. Nosske found many deposits of bone and cartilage in the deeper layers of connective tissue coating the tonsil. This author includes in etiology, inflammation, retrogressive changes and a sort of local predisposition. Recently, Zuckerkandl has declared that cartilage develops independently of the skeleton in the connective tissue of organs when mechanical relations demand the presence of such tissue, as, for instance, in the Eustachian tube. The author concludes by noting that the Eustachian tube is formed from the first bronchial arch; thus a part of the cartilage might be shut up in the tonsil.

New York Medical Journal, September 24, 1904.

Some Causes of Menstrual Disorders in the Girl.—R. S. Hill states that when from 75 per cent. to 90 per cent. of the girls entering young womanhood manifest an incapacity properly to discharge the functions peculiar to their sex, we should investigate the causes of this deplorable condition, and root out the evil which is sapping the vital force of so many of our girls. Attention is called to antenatal and postnatal factors. A study of the antenatal factors embraces the study of the laws of heredity. As a general rule, Nature protects best and first those parts of the body which are most essential to personal existence, or the preservation of the individual. He concludes that the sexual organs contribute less than any others to personal health, or individual existence; if this conclusion is correct, it indisputably follows that, in the development of the child, better provisions are made for the growth, anatomical and physiological, of all other organs than the sexual, and, therefore, if any organs suffer from general deleterious influences, these are usually the ones furnishing, as it were, the *locus minoris resistentiæ*. Attention is then called to the two most frequent sources of evil, viz., school life and tight lacing.

Immunity.—Anna M. Stuart says that antisepsis has given way to asepsis, and that asepsis is not the final word, for we often forget our greatest ally, the resistance of the tissues. The poor are delivered in safety, on a surgically clean bed, while we dread our fine class of obstetrical work. Any animal, including man, poisoned by diphtheria, goes to work to elaborate an antidote in its own tissues, sometimes successfully, at other times not in sufficient quantity. The antitoxin reinforces the deficient quantity. Following out this analogy, one is forced to conclude that small repeated doses of a poison do develop their own antidote in all our common germ diseases. Is the principle "away with germs," she asks, the true one? May we not by our efforts to avoid the germ, destroy the power of the blood to develop immunity, simply by lack of use, as any organ of the body after long disease, loses the power to functionate to greater or less extent? She believes that the typhoid fever patient, the pneumonia patient, and the tuberculosis patient will stand a better chance of developing his own antitoxin if we conserve his strength, and stop irritating his tissues with foreign substances. The chief point is that in our eagerness to destroy the germ, we forget to build up our chief ally, the immunity of the patient against that germ.

Some Unusual Forms of Acute Myelitis.—B. Sachs wishes the term acute myelitis to be understood to be a disease process causing a more or less rapid, or a more or less complete destruction of the substance of the spinal cord at any given level, excluding, however, those forms which are due to large hemorrhages, and to the breaking down of neoplasms. He reports one case in which there was every reason to make a diagnosis of acute transverse myelitis, from the clinician's point of view, and yet the autopsy failed to reveal the first sign of any inflammatory process. His special object, in referring to this case, was to draw an analogy between the cerebral and spinal vascular accidents of the senile period. It is curious that the vascular accidents which befall so many persons of advanced age, so rarely bring about disease of the spinal medulla. The spinal cord of the first patient shows arteriosclerotic changes, and the affection from which he died cannot be interpreted otherwise than a general degeneration of the spinal cord due to the affected blood supply. There was an entire absence of inflammatory conditions. A second case is reported, which was most unusual, because of the remarkable suddenness of the onset, such as one is accustomed to associate with hemorrhage into the cord. There was a simultaneous development of the cord affection and multiple abscesses, showing the septic character of the myelitis. In this case there was strong reason to suppose that it was a streptococcic myelitis from which recovery had been at least unusual, but by no means complete. Both cases reported were recorded merely for the purpose of insisting that the spinal cord does, at times, become the seat of similar morbid processes that occur in the brain, and he does not believe it will do to restrict the term of myelitis merely to the morbid process that can be distinctly traced to trauma, syphilis, and to the ordinary acute infectious diseases.

Summary of an Experimental Research into Strychnine in Shock and Collapse.—G. W. Crile states that, in the majority of instances, in the normal animal, when

sufficient amount of strychnine was given to cause an increased excitability of the spinal cord, a rise in blood-pressure was noted, and this stage of increased excitability represented the border-land between the dosage without effect, and that of maximum effect. When more was given after this stage had been reached, convulsions appeared, and the blood-pressure rose abruptly and high. The curve during the convulsions was exceedingly irregular and continued for some time above the normal, exhibiting a secondary rise, if later convulsions appeared. In a series of experiments in which the convulsions were prevented by curare, and in which convulsive doses of strychnine were given, the blood-pressure rose as high as in the experiments in which the convulsions did occur. In another series, both vagi and accelerantes were severed, curare given, and varying doses of strychnine administered. The general effect upon the blood-pressure did not materially differ from the effects of corresponding doses upon the normal animal. In the curarized animal, and in the animal having both vagi and both accelerantes severed, the rise following the physiological dose of strychnine continued from half an hour to one hour and a half. Successive repetitions of the dose caused rises, in each instance not so high as the previous dose, until a period was reached when no further effect was noted. After each dose the blood-pressure fell, after the effect had worn off, to a lower point than it was before the injection was given. When strychnine no longer produced a rise, no effect was noted on burning the paw, or electrically stimulating the sciatic nerve. After the blood-pressure had reached the stage of terminal helplessness, the administration of saline solution caused a rise, as also did the use of adrenalin; bandaging and other means of external pressure also caused a rise. In the animals in which both vagi and both accelerantes had been severed, no change in pulse rate was noted in any dose that was given. In animals in which varying degrees of shock were produced, strychnine caused a rise of blood-pressure proportional to the degree of the shock.

American Medicine, September 24, 1904.

Nerve Blocking to Prevent Amputation Shock; Illustrative Reports of Two Thigh Amputations.—Hermann B. Gessner reports these two successful cases. The first patient was a man of twenty-three years, suffering with tuberculosis of the right knee-joint and femur, with partial ankylosis. Amputation was decided upon, and when the posterior flap was being fashioned through the muscles, care was taken to identify the great sciatic nerve. This was infiltrated with 1.54 c. c. (25m.) of a 2-per-cent. solution of cocaine hydrochlorate, then divided at the infiltrated level. When the amputation was concluded, the great sciatic and the internal saphenous nerves were injected with the same solution on being drawn out for shortening. The pulse, which had been 80 when the patient was in the ward, by the end of the operation had fallen to 62. Its character was excellent throughout. Stimulation during the operation was limited to 2 mg. of strychnine sulphate, given hypodermically, just before the first nerve section. The writer believes that but 1 grain of cocaine was used. Of this quantity a large part must have been lost when the nerve tissue was divided. The second amputation was performed for chondrosarcoma of the right tibia. A good immediate result was obtained as to prevention of shock by the use of a 1-per-cent. solution of cocaine. There was a later rise in pulse, which may have been due to "delayed shock." In neither case was there any evil result from the blocking. The author states that he feels justified in recommending the method as one well worthy of further trial, promising much that is good, and so far showing no disadvantage. Five minutes would more than cover the time necessary for the blocking.

Garlic in Tuberculosis and Lupus.—John Knott gives a most interesting review of the history of garlic as a therapeutic agent. Even in the Middle Ages garlic enjoyed an excellent reputation for its curative properties. It is found three times in the verses of the famous "Regimen Sanitatis Salernitanum," which was addressed A. D. 1100 to Robert of Normandy, by the heads of the oldest European medical schools. Sir Thomas Browne gives a most interesting account of the therapeutic properties of this plant. The list of its curative properties is stated at such length, that, as the author says, the only remaining wonder is why sickness or death still remained—in presence of garlic! Some of its traditional therapeutic powers have been confirmed by modern science. Its objectionable odor is doubtless the cause of its having fallen into neglect. Koch states that the presence of a small percentage of allyl alcohol successfully inhibits the development of *Bacillus anthracis*. The "essential oil" of garlic is almost wholly composed of allyl sulphide. This oil is an intense rubifacient. In Ireland favorable reports have been made in regard to the administration of garlic in serious bronchial affections. Carazzani believes that a sufficient amount of garlic used in tuberculosis will produce immunity against infection. The writer expresses his hope that its uses in tuberculosis may be thoroughly investigated. He believes that its influence on the respiratory mucous membrane is due to the fact that the allyl compounds are so largely eliminated here. Garlic is bactericidal and presumably stimulating, consequently there are reasonable grounds for the hope that the traditional powers of garlic may be at least partly realized.

Tuberculosis of the Abdominal Lymph-glands.—Charles F. Painter and William G. Erving give as the three sources of tuberculous infection of the abdominal lymph-glands: 1. Direct extension from adjoining diseased tissues. 2. Infection from the blood stream. 3. Infection through the lymphatics. With a focus of tuberculosis in a lymph-gland, it is always a source of danger to the rest of the body. Often the fatal termination is due to complications. Complete intestinal obstruction, both chronic and acute, is not infrequent. Occlusion may follow secondary involvement of the wall of the intestine itself. Sometimes the glandular cyst-like masses reach enormous size, and rupture may take place through the peritoneum, giving rise to a local or general peritonitis. Often the mass of tuberculous detritus follows the general course of the psoas abscess of Pott's disease, and points either in the loin or in the thigh below Poupart's ligament, where it ruptures. As to differential diagnosis, the authors state that among cases with spinal symptoms, mesenteric tuberculosis must be distinguished from Pott's disease, aneurysm of the abdominal aorta, malignant disease, especially cancer, osteo-arthritis, osteomyelitis, and other inflammatory diseases in or about the spine. The writers consider the treatment of this condition under three heads: General, mechanical, and operative. The first is perhaps the most important and includes all factors which tend to build up the general system. Even when the spine is not directly involved there are many conditions in which fixation of this part affords relief from pain. As to the operative treatment, the same general rules hold good for the treatment of abscesses derived from broken-down lymph-glands as apply to abscesses from tuberculous bone lesions. As it is important to prevent them from becoming secondarily infected, incision should be delayed as long as possible. If aspiration can be safely practised, it is preferable to open incision. The writers have observed at operation an abdomen filled with glands so broken down and matted together that resection was impossible, but the patient, when seen two years later, showed absolutely no evidence from external examination of a pathologic condition of the abdomen. Much can be done to favor the prognosis in these cases, but their care requires great patience and perseverance.

The Lancet, September 17, 1904.

Cancer Facts and Cancer Fallacies: A Plea for the More Scientific Study and Treatment of Malignant Diseases.—Herbert Snow calls attention to the progressively increasing mortality from cancerous diseases in apparently all civilized communities. The common practice of grouping together a large number of diverse maladies under the single title "cancer"—no more definite and precise a term than "fever"—he believes to be fatally opposed to the interests of science. Classification, according to tissue origin reveals nine distinct *genera* of malignant new growth with thirteen well-marked *species*. Each of the nine owns a different mode of causation; and of every one the exciting cause is accurately known and clearly defined in technical works. Of what avail are arguments, researches, or statistical returns which bracket together such distinct varieties as an epithelioma of the tongue or lip, and a carcinoma of the mamma? and which, in addition, commonly designate both as "carcinoma." There is a distinction between the qualities of the neoplasm in each of the two maladies, now more or less confounded. He urges that an attempt should be made to place our knowledge of malignant diseases upon a truly scientific basis, and also that there should be placed on record authoritatively the facts we already know respecting their genesis and phenomena. Appended is a table showing the diseases known as "cancer," with their mode of causation.

Epithelioma of the Tongue in Women.—Charles R. Keyser says that this condition in women is decidedly uncommon, but the frequency with which it occurs varies apparently according to the sources from which the cases are derived. Age does not seem to differ in the two sexes. As in men, the disease is almost invariably preceded by prolonged local irritation. The precancerous condition or leukoplakia is commonly seen, and runs a course identically the same as in the opposite sex. Syphilis is by no means a constant precursor of epithelioma of the tongue. Appended are reports of ten cases.

Congenital Word-Blindness.—Sydney Stephenson says that so far fourteen cases of word-blindness have been reported by six authors, but he states that these cases are not so rare as the scarcity of records might lead one to infer. The writer places on record two cases, one slight, the other severe, that had fallen under his notice. It cannot be doubted that there exists a congenital condition where the learning of letters or of words from printed or written characters is difficult or even impossible. This may be due to some defect in the visual memory center for words and letters. Males were affected in 82.25 per cent., and the ages of the patients averaged thirteen years. Vision was normal in all but two, and the general intelligence was good in thirteen of the sixteen cases. The improvement in these cases was generally described as "slow but satisfactory." The diagnosis offers but few difficulties unless the condition coexisted with a considerable error of refraction. Congenital alexia, he believes, will be found to be commoner than hitherto supposed.

Case of Spontaneous Gangrene of the Skin in an Hysterical Woman.—W. A. Mearns reports the case of a woman, twenty-four years old, very anæmic, delicate, and known to be of a hysterical disposition, with a skin lesion on the lower part of the neck and just above the middle third of the right clavicle. The area involved was rather larger than a half-crown piece, and its appearance had been preceded by a hot, burning sensation. One week later the part was seen to be quite black in color and evidently gangrenous; on raising the surface slightly a sloughy débris of pus-like matter could be seen. Boric acid fomentations were applied, and soon the slough separated and left a raw, red surface exposed. Two successive areas of skin were involved, extending from the original spot up toward the right ear. The same cycle of changes were here noted, ending in gangrene. The appearance was exactly as if the skin had been burned with a corrosive acid. Thereafter the lesions extended progressively below the clavicle down to the right breast, in all there being about seven distinct areas affected. Gradually all the sloughs were removed by fomenting, and a large raw surface was left extending from just below the right ear down to the right breast. Convalescence was very slow and protracted. The cicatrix broke down several times when nearly healed. After five months in the hospital, she was discharged with an exceedingly large disfiguring cicatrix on her neck and breast.

British Medical Journal, September 17, 1904.

Evanescent Subcutaneous Nodules Accompanied by Eruptive Fever in a Patient from Southern India.—James Cantlie on examining this patient, learned that for many months he had had several nodules about the size of No. 6 shot beneath his skin. Each nodule was accompanied by a slight increase in temperature, and caused a little irritation and local redness. The nodule lasted about three weeks, at the end of this period all local traces disappeared. The nodules had developed in the upper and lower limbs. The skin was slightly adherent to the nodules, but these moved freely on the deeper tissues. There were no filarial embryos in the blood. Examination of the nodules also revealed no worm. Microscopical sections showed newly formed connective tissue, embryonic in nature, with a number of dilated lymphatics or lymphatic spaces in the center. The writer declares that he is convinced that the disease was an evanescent obstruction of th lymphatic in the limbs.

Lymphoid Cells.—James M. Beattie, in describing the cells of lymphoid tissue, says that they are like the cells of lymphatic glands. They are small; the nucleus is rich in chromatin; usually it is round and central. The staining is so dark that very little structure can be made out in the nucleus. The protoplasm is generally very scanty, and takes on a reddish stain with eosin. In dealing with the function of lymphoid cells, not only the small forms, but the larger ones which are derived from them, must be considered. The writer has never seen phagocytosis by the smaller forms, but he states that the larger forms and the plasma cells are doubtless phagocytic not only to foreign particles, but also to other cells and bacteria. The mononucleated phagocytes are the most important of the cells of inflammatory exudations. In the healthy peritoneal fluid and in the later stages of infection, where recovery is taking place, they are almost the only cells present. In all of the writer's experiments, in which the animal recovered from infection, the mononucleated cells became greatly increased, as compared with the polymorphonuclears, from about 30 hours onward. In fatal cases, the polymorphonuclears were always in excess. The writer's observations lead him to think that these lymphoid cells in repair and in tubercle granulations are capable of producing fibroblasts and fibrous tissue. But, nevertheless, he is convinced that their rôle here is a very secondary one. The fibroblasts are formed, at any rate, principally from the fixed cells of the part. Most of the lymphoid cells apparently are destroyed in the newly-formed tissue.

The Congo Floor Maggot, a Blood-sucking Dipterous Larva Found in the Congo Free State.—J. Everett Dutton, J. L. Todd and Cuthbert Christy in describing this maggot, tell how the natives collect them by digging with the point of a knife or scraping with a sharpened stick in the dust, filled cracks and crevices of the mud floors of their huts. Many were turned up from a depth of three inches. In moist, soft earth, they are found even at greater depths. There is no doubt that these maggots feed only at night. The natives said that the maggots drop off at once if the limb on which they are feeding is moved. There were specimens of all sizes, ranging in length from 2 to 15 m.m. When ready to pupate, the larva lies dormant upon the surface, changes in color to a pinkish-brown and later becomes a dark reddish or brownish-black, chitinous, segmented, with oblong paparium. The natives believe that the maggot is able to jump to a height of 18 inches, but the authors have never been able to substantiate this. It probably feeds nightly, for blood in varying stages of digestion, and ranging in color from bright red to black, is often seen in its alimentary canal. The writers think that the maggots reach the raised beds by crawling up either the supports or the grass wall against which the bed is usually placed. The distribution of the larva is very extensive. This larva maggot is semitranslucent, of a dirty white color, cephalous, and amphipneustic. It resembles, when adult, the larvæ of the bot-flies, and consists of eleven very distinct segments. Paired groups of minute spicular teeth are placed around two tenacula so as to form a sort of cupping instrument. The integument of the larva is tough and thick. The larva can stand a great deal of pressure without injury. The time required for the maturation of the larva is not yet known. The writers saw a large light brown fly which is believed by some observers to be developed from the floor maggots. The writers have allowed a number of these maggots to feed on rats and guinea-pigs. They mean to determine whether they are able to play a part in the transmission of the human trypanosome. They have not been able yet in any entomological works which they can command, to find any reference to the habits or morphology by which this fly can be identified. E. E. Austen, dipterologist to the British Museum, states that these flies are specimens of *Auchmeromyia luteola*, Fabr. (a species of the family *Muscidæ*). He declares that the writers of this article have come across an entirely novel and very interesting fact in the biology of diptera.

Leprosy a Curable Disease.—T. J. Tonkin believes that it is the same with leprosy as it is with tuberculosis. He speaks of the well-known fact that at autopsy old tuberculous lesions are frequently found in patients who have died from another cause entirely. Every grade of leprosy exists. Many patients may recover without any more than suspecting the nature of the malady with which they are affected, or even without suspecting it at all. Among the severer cases, the occurrence of some improvement in their circumstances, almost always betters the individual's condition, and in some of the cases abolishes the disorder. The writer states that the average period of fatal leprous disease is not often longer than twelve years. Of over two hundred cases that he has examined, 24 per cent. had survived fifteen years, while 8 per cent. had left the invasion period from twenty to fifty-five years behind. The effects of the disease may remain—as mutilated fingers and toes, but the writer believes that if the patient is devoid of the signs and symptoms of the active disease, if his organs are performing their functions in an ordinary manner, if he enjoys life and can work, then it is rational to consider him hale, and if the accessible fluids of his body are free from bacillary pollution he can hardly be regarded as a danger to the community. That in this sense leprosy is curable there can be little doubt, for many individuals of this description are living. It is important to recognize the curability of the disease, for if this fact is not recognized a community will not be apt to look with favor on an asylum for lepers which discharges its patients. If this disease is considered incurable, it is not likely that any educational movement will be instituted to correct the prejudices of the people. Again, the patient himself, in the institution, believing himself to be beyond hope, will not avail himself of any of the aids which in the early stages of the disease offer such golden opportunities for treatment. Owing to this general belief, large numbers of leprous persons are rendered ineffective as wage-earners. Taken early it is possible that the man can not only be cured, but that he will be able to go back again to take his original place in the world. The writer finally speaks of the responsibility of the medical profession in this matter, which he believes is not small. He believes that sooner

or later his ideas concerning the curability of this disease will be acknowledged; but that time will then be too late for many victims who are now in the first stages of this disease.

Deutsche medizinische Wochenschrift, September 1, 1904.

Beck's Operation for Hypospadias.—C. Bötticher reports on the results obtained by this procedure, which consists of freeing the urethra, then displacing it forward and suturing it to the edges of a new meatus, formed by an incision directly into the gland. Of ten cases, six were examples of glandular hypospadias, and the remainder penile hypospadias. It was found preferable to tunnel the glans rather than to split it, both of which are recommended by Carl Beck. For the erections which are liable to occur after operation, a few drops of tincture of opium afforded most relief. The writer claims that the best time for operating is during the third year, as the parts are easier to handle and easier to keep clean.

Dangers of the Bottini Operation.—P. Rosenstein calls attention to an accident which may occur during this operation, to which insufficient notice has been extended, namely rupture of the bladder. He instituted a number of experiments with reference to the changes in the intravesical pressure, in an endeavor to arrive at an explanation of this complication. In the case reported, the bladder was distended by about 200 c.c. of air, and ruptured without warning, during the course of the operation. The organ was repaired through a laparotomy incision, but the patient died on the eleventh day of bronchopneumonia. A number of physical experiments were made by the author, and in the first of these he was able to prove that the rupture could not take place from the mere heating of the air contained in the bladder, as has been claimed. When moist organic tissue was heated by the "incisor," a bursting of the glass globes, intended to represent the bladder in the experiment, took place, and a pressure of two atmospheres was registered. As the "incisor" enters the substance of the prostate gland, small globules of water collect on the blade, surrounded by a layer of steam. As the instrument is slightly cooled by the tissue, the water drops suddenly become steam, and a consequent increase in the pressure results in the bladder. These experiments were confirmed by observations carried out in animals and the cadaver.

Berliner klinische Wochenschrift, August 29, 1904.

Employment of Filter Paper in Hæmatology.—Tallyquist comments on the value of white filter paper in making a diagnosis of anæmia, when used in connection with the author's hæmoglobin scale. A phenomenon to which he calls attention is the formation of a ring of moisture around the red stain itself, which becomes visible on holding the paper up to the light. This always points to a marked diminution in the number of the blood corpuscles, and has been determined as appearing whenever the number falls to one-half the normal or less. The greater the diminution, the more extended the ring. Another disease of the blood which may be recognized is leukæmia. In sharp contrast to normal cases, it will be found that the filter paper takes up the blood drop with difficulty, and considerable time is consumed before the spot is dry enough for the purposes of the comparative color test. The color, moreover, is uneven, and does not correspond with any one of the colors on the chart. This condition is probably due to the unusually large number of leucocytes present.

Enuresis in Children.—J. G. Rey states that the views regarding this complaint may be classified as follows: (1) That enuresis is nothing more than an anomaly of function in an otherwise healthy child with a normal urinary apparatus. (2) In opposition to this is the view that every case depends on a pathological basis which may result from one or a number of causes. (3) A combination of these two views: The author has carried out an extensive series of investigations with the urine of fifty-two patients, and has arrived at the conclusion that in the majority of instances the trouble is due to a disease of the bladder or the neighboring organs, unless there is no lesion of the central nervous system, idiocy, or athyreosis. Enuresis must be considered a physiological condition during the first ten months of life, but if it extends beyond this and continues beyond the third year of life, there is present, in addition to the direct or indirect irritation of the bladder, a diminsshed will power. Where the children have suffered from ionie disease of the bladder during their early years, the enuresis becomes a matter of habit, but the effect on the will power may persist for a long time after the bladder symptoms have disappeared. In order to clear up the etiology in any given case of enuresis, it is necessary to make frequent chemical and bacteriological examinations of the urine, and in older children, to institute an endoscopic examination if possible. The treatment is mainly dietetic, milk in the form of soups and gruels having been used by the writer with considerable success. Meal times should be regular, and nothing given in the interim. A bitter tonic with HCl is given before meals and, for the vesical irritation, salol in moderate doses after meals, together with strychnine in older children. Exposure of the genital region and cold feet must also be avoided.

Münchener medizinische Wochenschrift, August 30, 1904.

Unusual Injury to the Middle Ear.—M. Scheier reports a case in which there was an isolated injury to the anvil with complete exfoliation of this bone. Nothing of this kind has hithe to been observed. A woman on cleaning her ears with a hair pin wrapped in a towel, was suddenly seized with severe tinnitus and vertigo. There was complete deafness on the injured side. Examination showed a perforation of the drum and in the canal was found a perfectly normal anvil. No otitis media followed as might have been expected and the woman recovered but with hearing only partially restored and some tinnitus still present.

Hydrophobia and Trauma.—Ed. Pfister describes an interesting case in which trauma evidently played an important factor in producing a recurrence of a hydrophobia. The patient was bitten by a dog, which later developed true hydrophobia, and had also bitten a number of other persons. All these were treated by the Pasteur method at the institute in Cairo, Egypt, where the occurrence took place, and made a good recovery, including the individual first noted. About three months later, the latter was forcibly struck on the head and sustained a severe scalp wound, which promptly healed, however, under appropriate treatment. No fracture of the skull could be made out. Within a few weeks the man began to act queerly and his general condition became one of melancholia with marked depression. Then he began to complain of pain on swallowing, which grew rapidly worse and was accompanied by spasm of the œso hagus. Deglutition, especially of cold articles of food, soon became impossible. These, in combination with other signs, designated the case as one of hydrophobia, without prospects of recovery, and the man died shortly after. The writer suggests as a possible explanation of this case, that the virus, in a latent condition, remains localized in the bulbus and certain other parts of the brain nearby. A blow which affects this region might set free the toxin and distribute it through the brain. In this case the infection might have been favored by the fact that the patient presented a hereditary history of mental disease, which is known to be a contributory factor in the production of hydrophobia or other cerebral diseases.

Retrograde Metastatic Currents from the Thoracic to the Abdominal Cavity by the Lymphatics.—Tendeloo calls attention to the changes which may be present in the retroperitoneal lymph nodes and account for the transmission by the lymphatic channels of material from tumors and infectious processes in one cavity to the other. There are several groups of these nodes, and the one to which he has paid particular attention he designates the para-aortal group. His observations are largely based on autopsy findings and the present discussion is limited to metastasis from the thoracic to the abdominal cavity. In a number of cases of pyopneumothorax, a purulent adenitis of this para-aortal group could be made out, while the mesenteric and the remaining abdominal nodes are unchanged. The same was noted in pulmonary tuberculosis. This localization seems to confirm the supposition that the path of the infection was through the lymph rather than through the blood channels, for if the latter were true there is no reason why the infection should not have been more widespread. Four cases of mammary carcinoma were also examined, in which the involvement of the surrounding parts was quite extensive. In one case no abdominal metastases were found, in two the nodes around the lower end of the aorta were involved, and in the fourth case, there were deposits in the liver and the portal lymph nodes. It is also likely that here the extension was through the lymphatics. Scattered through the nodes around the abdominal aorta in certain cases, pigment was found which on careful examination was determined to have originated outside of the body. The lungs also contained it and it therefore seems reasonable that this inhalation pigment found its way through the lymph channels from the lungs to these retroperitoneal glands. In some instances the pigment could even be detected in the diaphragm.

French and Italian Journals.

Chronic Pleurisy with a Large Osteoid Plaque.—Pelletier reports this interesting case. The patient, who had been admitted to the hospital for aortic insufficiency, died suddenly. At autopsy it was discovered that the left lung

which was decidedly atrophied, was completely adherent to the chest wall, being attached by fibrous adhesions. There was no pleural cavity. A very hard plaque was found in the parietal pleura. This plaque measured about ten cm. by five cm. Nearly always these induration pleural plaques are calcareous, but in this case the consistence of the tissue is decidedly like bone. A histological examination will probably be made to prove this point.—*Bulletins et Mémoires de la Société Anatomique de Paris*, April, 1904.

Gastroenterostomy for Gastric Ulcer or Cancer.—Depage has kept records of the history of eight patients operated upon since the beginning of the year for various affections of the stomach. He used Roux's "Y" method of gastroenterostomy in all of the cases, confining himself to two rows of sutures. The operation took from thirty-five to forty-five minutes. The results were very satisfactory. There were four cases of gastric ulcer, three of pyloric cancer; while in the eighth case there was cancer of the pylorus adherent to the abdominal wall and to the transverse colon. In this last case, the tumor was resected "en masse" without any difficulty. The writer then gives a short summary of the cases, showing the marked improvement in the general condition of the patients since the operation.—*La Policlinique*, August 1, 1904.

The Persistence of the Klebs-Loeffler Bacilli in the Throat of Children Who Have Had Diphtheritic Angina—B. Auché sums up his conclusions as follows: (1) In cases of diphtheritic angina, the Klebs-Loeffler bacillus may persist in the throat three and even four weeks after the disappearance of the false membranes. (2) In general, it is transformed, and becomes shorter and less virulent in proportion to the length of time that it remains in the throat. (3) It may, however, grow again, and cause a relapse, or be transported to the throat of another person, and give rise to an acute attack. All such chances should be avoided. (4) The only way to prove the time of disappearance of the bacilli, is to make cultures on gelatinized serum. The patient should be isolated until the culture gives a negative result.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, August 14, 1904.

Cure of Alcoholism.—Legrain reports on the method of treating alcoholics in Russia by hypnotism. In some of the cities in that country there have been for some years instituted under the auspices of the government, dispensaries or sanitariums where hundreds of patients flock. The treatment is gratuitous, and hypnotism is, if not the only, at least the principal therapeutic agent. It is demanded of the patients that they sincerely desire to be cured, and that they abstain from all spirits while they are under treatment. This is asking a great deal of these patients, and requires of them a tremendous effort, especially as very often their volition is almost abolished. They are subjected, also, to a continual surveillance. Nevertheless, hypnotism remains an extremely valuable and efficacious means in the cure of alcoholism. It gives good direction to the mental processes, and the necessary vigor to maintain the good resolution not to drink. In order to avoid relapses it is neessary to enroll the alcoholics in societies of abstinence or temperance.—*Archives de Neurologie*, August, 1904.

The Actual Status of Radiotherapy.—M. J. Bergonié reports a case of tumor of the face of long standing which had resisted all medication. The histological structure of the tumor is not noted. The patient had been treated by a distinguished dermatologist, but to no avail. The growth increased rapidly from day to day, and had encroached upon one side of the nose as well as involving the tissues both above and under the eye. This tumor was cured by means of radiotherapy after eight treatments. It is now three months since the last treatment was given, and the patient has stadily improved. She has begun to be able to raise the eyelid, and there is no trace of recurrence. However, as the writer adds, the results in all cases are by no means so happy. In one case of rodent ulcer, there was absolutely no relief after twenty sittings. The inflammatory reaction is the first good sign in cases treated by radiotherapy. The writer believes that radiotherapy is a means of treatment particularly efficacious in certain skin diseases, and in nearly all cases of cutaneous epithelomata. Aside from the good results obtained, another advantage of this method is its absolute painlessness.—*Journal de Médecine de Bordeaux*, August 14, 1904.

Abscess of the Posterior Mediastinum.—Piet cites this case which came under his observation. The patient was a woman fifty-seven years old, and entered the hospital for what she believed to be an obstruction in the œsophagus. She thought she had swallowed a piece of bone which had lodged there. The œsophagus was carefully explored, but nothing was found in the nature of a foreign body, although the bougie met with a resistance at about the junction of the middle and lower thirds of the tube. The symptoms increased in severity after the exploration. Pain, agonizing dyspnœa, and cardiac collapse made the patient's condition very grave. The temperature also rose. The patient died a week after entering the hospital. Autopsy revealed an abscess in the posterior mediastinum. It was as large as a hen's egg, and a little to the right of the median line. It reached below almost to the diaphragm. The result of the autopsy explained the symptoms of the patient satisfactorily. But the pathogeny of the abscess did not appear. There was no perforation of the œsophagus, nor was there any focus of peribronchial gangrene. The case is obscure, and interesting on account of its rarity.—*Journal des Sciences Médicales de Lille*, August 6, 1904.

Vaginal Hysterectomy for Cancer of the Cervix During Pregnancy.—R. Condamin and A. Condamin present the following conclusions: In the case of operable cancer of the cervix, determined during the course of pregnancy, intervention is the duty of the surgeon, for by practising total hysterectomy in time, there is a chance of saving the mother; 22 per cent. of non-recurrences after four years is the record of cases reported in this article. The chances of survival of the fœtus, if pregnancy is not disturbed, are very small. If the parametrium (the broad ligaments, and vesical wall) is invaded, if it be even slight in extent, the mother is doomed. The infant will then be the only object of interest. During the sixth or seventh month of pregnancy, if the cancer has just started, and if the surgeon thinks that by waiting a month or two he will be able to perform a radical operation, he may await the viability of the fœtus. But on the contrary, if the cancer is then operable, intervention should be practised without regard to the fœtus. Vaginal hysterectomy may be done by the classic method. But the infant ought to be extracted by abdominal cæsarean section. It would be necessary to combine the two methods to give both mother and child the best chances.—*Lyon Médical*, August 7, 1904.

So-Called Cystic Cystitis.—Umberto Parodi tells us that cystic degeneration of the wall of the bladder is exceedingly rare. The patient whose case he reports had atheroma of the aorta, and peripheral arterial sclerosis, bronchitis and pulmonary œdema. The pelvis of the kidneys was normal, as well as the ureters, and the urethra. The bladder walls were contracted and presented a slight grade of cystitis, with marked cystic degeneration of the sub-mucosa. The cysts were the size of a grain of millet, scattered over the surface, but most frequent in the postero-superior portion. On microscopic examination solid epithelial nodes were noticeable, with a tendency to degeneration in the center. Other nodes had become cystic by continuation of the degenerative process; the cavity of the cysts was filled with amorphous material, and degenerated epithelium. The nodes and cysts were independent of the vesical epithelium; there was only a slight degree of inflammation of the mucosa of recent origin; there was nothing to account for the origin of the cysts from chronic inflammation; they had not the characteristics of true adenomatous formation; and they were not localized in any one portion of the bladder, but distributed over its surface. The author believes them to have been developed from congenital epithelial nodes.—*Archivio per le Scienze Mediche*, Vol. XXVIII, Fasc. 1, 1904.

Paratyphoid Fever.—Raoul Bensaude and Lucien Rivet in a paper on this subject pays special attention to the history and symptoms of this disease—touching on the diagnosis. Paratyphoid belongs in the large family of general severe infections. It is much like typhoid fever not only clinically, but also from the bacteriological point of view, for the paratyphoid bacillus is closely related to the bacillus of Eberth. The clinical resemblance between these two fevers is so close that the differential diagnosis is possible only after bacteriological researches are made, which show in the case of paratyphoid: (1) The absence of, or at least the feeble intensity of Widal's agglutinative reaction; (2) The presence of the paratyphoid bacilli in the organism, especially in the blood. (3) The agglutination of these bacilli by the serum of the patient. The name "paratyphoid" was given to these bacilli for the first time by Achard and Bensaude, in 1896. The paratyphoid bacillus, like the bacillus of Eberth, can give rise, clinically, to local infections which are rare; and to general infections with the form of ordinary typhoid. In a large number of cases, the symptoms for the first few days are vague—headache, general malaise, anorexia and abdominal pain being characteristic. Constipation is the rule. Albuminuria is sometimes present. The diaoz reaction is present in only 30 per cent. of the cases. The temperature is highest in the evening. These are the diagnostic points of most value—*Gazette des Hôpitaux Civils et Militaires*, August 13, 1904.

Book Reviews.

Medical Tuberculosis; Its Rational and Natural Cure; Its Several Stages and Relationship to Cancer. By R. B. Searle, L.R.C.P., M.R.C.S., L.S.A., Mayor of Dartmouth. London: The Scientific Press, Ltd., 1904.

The writer advocates the introduction of the typhoid bacilli with their toxins into patients afflicted with tuberculosis which is passing into the third stage. He believes that cancer may be looked upon as a malignant variety of tuberculosis. He states that his treatment requires skill, intelligence, experience, and conscientiousness.

Über den Schluckmechanismus. Von Prof. Dr. J. Schreiber. Berlin: A. Hirschwald, 1904.

In this very valuable monograph Schreiber has published a series of important experiments on the act of deglutition. Meltzer's works on this subject are fully discussed. Schreiber arrives at the conclusion that solid as well as liquid substances reach the stomach by the peristalsis of the œsophagus, and not by any act of throwing from the pharynx directly into the stomach. The experiments of Schreiber certainly deserve careful study.

The Brain of the Sheep. Part IV, Revised, of Physiology Practicums. Third Edition. By Burt G. Wilder, B.S., M.D., Cornell University. Ithaca, published by the Author, 1904.

This pamphlet contains explicit directions for examining the brain of the sheep as an aid to the study of elementary physiology. It is in the form of practical lessons and well illustrated by the author's characteristic drawings. The concise exposition of the various features in the anatomy of the brain will greatly aid the student in his dissections of this organ.

Précis de Thérapeutique Oculaire. Par le Docteur Scrini, Chef de Clinique Ophthalmologique de la Faculté de Paris à l'Hôtel Dieu. Préface du Professeur de Lapersonne. Paris: G. Steinheil, 1904.

The book is one of 322 pages and, in addition to the work of Dr. Scrini, it contains a short preface by Professor de Lapersonne. It takes up the consideration of the sterilization of instruments, the methods of rendering the hands of the operator, and the site of the operation aseptic, as well as a consideration of the various remedies employed in the treatment of diseases of the eye.

A chapter is devoted to a discussion of the merits of the various general and local anæsthetics employed in eye surgery. The various drugs used are discussed, as is also the method of their application. The value of physical applications is considered—dry and moist heat, dry and moist cold applications, electricity, magnetism, and light. Mechanical appliances and mechanical measures, such as bandages, protection shields, massage, brossage, and the surgical treatment of trachoma, are briefly described. Remedies that are employed systematically to influence conditions of the eye are also mentioned. The use of different sera is given full consideration. Throughout the greater part of the work the general application of remedies is considered, and at the end some twenty pages are devoted to the therapeutics of special diseases of the eye. As stated by the author in his introductory remarks, the volume reflects the practice, as far as therapeutics is concerned, of the Ophthalmic Department of the Hôtel Dieu under the supervision of the late Professor Pannas. The work is one of value to all ophthalmologists.

Ueber Immunität der Syphilis nebst Bemerkungen über Diagnostik und Serotherapie der Syphilis. Von Dr. Franz Nagelschmidt. Berlin: August Hirschwald, 1904.

This brochure represents the original investigation of the author carried out in Lesser's laboratory in Berlin; in that of Neisser in Breslau, and in his own private laboratory since 1900. The result would point to syphilis as conferring a certain immunity to the individual affected, and the hope of finding a therapeutic serum is strengthened. The animal experiments given with brief detail and conclusions, will interest many workers in these fields.

First Report of the Tenement-house Department of the City of New York. Vols. I and II.

These two volumes report in full the organization, problems and results of the department during the period between January 1, 1902, and July 1, 1903. The relations between the other city departments and itself, the workings of the new tenement-house laws, the laws and regulations, and the results obtained are all described in detail and make most interesting reading. As a guide book for other cities contemplating a similar department it would be indispensable. The illustrations describing the conditions existing before and after interference are many and instructive. All those interested in humanitarian effort and social conditions should read the work, and can be sure that their time will have been well spent in so doing.

Traitement de la Tuberculose Pulmonaire par la Médication Intra-trachéale. Par le Dr. Henri Mendel, Ancien Interne des Hôpitaux. Introduction par M. le Professeur Brissaud. Deuxième Édition, remaniée et augmentée (avec 7 figures et 26 tracés pneumographiques). Paris: F. R. Rudeval, 1904.

The author explains the method of treatment of tuberculosis which he has already presented to the medical public in several communications and in a first edition of this book in 1900. Since that time he has perfected the method and simplified the technique. The medicament for injection used by him is a solution of eucalyptol in olive oil. This substance, though active, is inoffensive. It does not give rise to unpleasant symptoms, but rather diminishes them. The treatment of tuberculosis by these tracheal injections, the writer believes, gives better results than are obtained by other methods. He claims to have had himself excellent success with it. The book is clearly illustrated.

Diagnosis from the Eye. A Scientific Essay for the Public and Medical Profession. By Henry Edward Lane, M.D. Chicago: Kosmos Publishing Co., 1904.

This ridiculous book pretends to describe a new art of diagnosing with perfect certainty, from an inspection of the iris, the normal and abnormal conditions of the organism in general and of the different organs in particular. The author seems to believe that all morbid conditions can be detected in an examination of the eye, no matter what their origin, as every organ is represented in exactly defined parts or sections of the iris. Based on this he has constructed a key, with the aid of which diagnosis should prove a simple matter. There is also appended a chapter on the method of "natural treatment," containing a number of puerile assertions, such as the statement that scabies has its origin in an impure state of the blood, the itch mite merely being a secondary factor. The book furnishes a certain degree of amusement, but otherwise does not merit shelf room.

A Clinical Handbook of Urine Analysis. By Charles H. Bedford, D.Sc., M.D. (Edin.), Professor of Chemistry, Calcutta Medical College; Consulting Chemist to Government of India, Calcutta; Chemical Examiner to Government, Bengal; Major, Indian Medical Service; Author of "Practical Chemistry (Qualitative), Inorganic and Organic," "The Symptoms and Treatment of Poisoning," etc., formerly Professor of Chemistry, Lahore Medical College; Chemical Examiner to Government, Punjab; and Editor *Indian Medical Gazette*. With Illustrations. Second Edition. Edinburgh: Bell & Bradfute; London: Simpkin Marshall, Hamilton, Kent & Co., 1904.

The first edition of this work was published only in India. The present edition has been enlarged by about sixty pages. An entirely new set of illustrations has been prepared for it. The author states that the methods herein described are considered to be those most suitable for clinical requirements. The volume is a valuable on for practitioners.

Beitrag zur Pathologie und Therapie der Pankreaserkrankungen. By Dr. Paul Lazarus, Priva Docent in Berlin. Berlin: Aug. Hirschwald, 1904.

This monograph is an extended and amplified reprint of articles which have recently appeared in the *Zeitschrift fur klinischen Medizin*. It contains an extensive review of the literature and the author's own observations, with especial reference to the question of pancreatic cysts and calculi. The first part of the book is devoted to pancreatic cysts, and fourteen cases seen by the author are reported in detail. The clinical picture presented by this class of cases is very varied and depends on etiology, the anatomical origin and the mode of growth. He has found that the diagnosis depends on determining the presence of a fluctuating retroperitoneal tumor, springing from the epigastric or left hypochondriac regions, and accompanied by disturbances of the pancreatic function. In the section on calculi he refers to his experiments in dogs, where he endeavored to produce calculi by producing secretory stasis, by infecting the pancreatic passages, and by a combination of these two procedures. The experiments showed that there was a close connection between duodenal catarrh and pancreolithiasis, and that a lesion in the epithelium of the ducts or acini and a change in the secretion is necessary before stone formation can take place. The symptomatology, prognosis, and treatment of pancreatic cysts are fully discussed, and although therapeutic measures directed against this condition are still imperfect, rational methods are now being developed, thanks to the achievements of experimental pathology and abdominal surgery. The work is timely and interesting.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Seventeenth Annual Meeting, Held in St. Louis, September 13, 14, 15, and 16, 1904.

Dr. Walter B. Dorsett of St. Louis, President.

An address of welcome, on behalf of the St. Louis Obstetrical and Gynecological Society, was delivered by Dr. Louis E. Newman.

The remarks of Dr. Newman were followed by an interesting and instructive address by David R. Francis, President of the Louisiana Purchase Exposition.

The response to these addresses of welcome was made by Dr. L. H. Dunning of Indianapolis, Ind., and Dr. Herman E. Hayd of Buffalo, N. Y.

Operative Treatment for Painful Menstruation in Young Virgins.—Dr. Wm. A. B. Sellman of Baltimore, Md., read a paper with this title. The author pointed out the great necessity of giving relief to young unmarried women who suffered from painful menstruation. The forms of dysmenorrhœa that could be relieved by the operative means suggested were expatiated upon at length. These means should not be of a character to unsex the patient or prevent her from bearing children or from fulfilling her marital relations. The operation should not be one which would endanger life or interfere with the woman's general good health. To illustrate the condition and to demonstrate the manner in which cases could be operated upon without unsexing the individual and giving absolute relief from the suffering experienced, the author related the following case in which he operated in the early part of June, 1904: Miss H., aged twenty-four, a brilliant vocalist with a register of three octaves, had been unable to use her voice with any satisfaction for a long period on account of the pain developed in the ovarian region when attacking the high notes. June 7, 1904, under ether anæsthesia, the author curetted the endometrium, removing a quantity of congested tissue from the cavity of the uterus. He then made an abdominal incision in the median line and found both ovaries hyperæmic and distended. Upon the left side he opened three good-sized cysts and upon the right side two medium-sized cysts. The Graafian follicles in each ovary were distended. He enucleated these with a sharp spoon curette and scraped the walls of the cysts in order to destroy the germinal membrane. He then closed these openings with catgut sutures and used the same material with which to close the opening in the abdominal wall. The patient made an uninterrupted and rapid convalescence, and had not had the slightest amount of pain in the ovarian region, and no pain during two menstruations which she had passed through, since the operation. He thought very many gynecological surgeons would have removed both ovaries under these conditions, and the result would have been the unsexing of the patient and probably the loss of her voice, especially in the upper register. He had heard her sing, and he was certain that her voice had not been impaired in the slightest degree. Two physicians present during the operation, when they saw the condition of the organs in the pelvis, expressed the opinion that no relief would follow unless he performed the radical operation, and removed the appendages completely. Resection of the ovary was followed by such successful results that one was not justified in removing the organs unless the complications present gave no opportunity to perform the conservative operation. Lastly, the author spoke of that class of cases in which dysmenorrhœa was due to a general systemic neuralgic condition. In these cases one at times secured great relief by the use of the various forms of electricity. It was doubtful, in many of the cases, whether removal of the appendages would accomplish anything more than to bring about a premature change of life, and the patient would remain just as nervous as before she was operated upon. The author exhibited three sizes of reamers devised by himself, which he had used for examinations for ten years. In not a single instance, when handled properly, had he witnessed any injury inflicted by them, and he had a record of a large number of instances in which by the use of these instruments he had succeeded in overcoming the condition of stenosis or obstruction when every other means had failed.

Dr. H. W. Longyear of Detroit, Mich., stated that in operating, if one could save an ovary or part of an ovary, he should do so. But sometimes one might have to operate again. In the majority of cases one could conserve tissues there with perfect safety, and with the result of allowing the woman to menstruate as she would in a normal condition. He would enter a protest against operating upon cases of dysmenorrhœa that were of short duration in young persons. One should not subject any unmarried woman to an operation if it could be avoided. The minor cases of pain of short duration did not need operative measures.

Dr. Herman E. Hayd of Buffalo, N. Y., alluded to the importance of examination in these cases, and even after an examination was made one might find that the most distressing cases were the ones that practically had no evident pathology which could be made out by such an examination. On a previous occasion the speaker read a paper on this subject in which he pointed out that retrodeviation of the uterus was responsible for much of the dysmenorrhœa in unmarried women.

Dr. William H. Humiston of Cleveland, Ohio, said he had not been able to find a case of dysmenorrhœa that was not accompanied by an inflammatory condition of the mucosa. He had seen cases of narrow, conical os, with the patients menstruating without the least sign of distress, but the moment there was an inflammatory condition of the mucosa added to that, that moment the patient began to have painful menstruation. In cases of this kind he thoroughly dilated the uterine cavity, curetted, and had the patients wear an Etheridge pessary, closely watching them for several months, and if there was no accompanying disease of the appendages, the cure was decided and complete. But in these cases occasionally one would have a failure because of failure to recognize the cirrhotic ovary, which was hard to detect unless an examination was conducted under an anæsthetic. In these cases there was no relief afforded except by removal of these shriveled, corrugated, smaller than normal ovaries.

Dr. D. Tod Gilliam of Columbus, Ohio, spoke of the undeveloped condition of the uterus as a cause of dysmenorrhœa. A great many men had come to the conclusion that it was not a superficial condition; it was not produced by the condition of the mucosa, as a rule; it was not the result of stenosis of the internal os or of many of the other orifices of exit, but was due to the undeveloped, unripe condition of the uterine tissues. The uterine tissues were just like unripe fruit, and one of the functions of the uterus was to throw off this membrane at stated intervals, and in doing so there were certain physiological processes that must work their way or be concerned therewith. Unripe fruit was hard to dislocate. If one tried to pick an apple from a tree before it was ripe, it would not come away very easily. If one stripped the capsule from any fruit which was not ripe, it was not easily done, but when it was ripe it would come away almost of itself. It was the same way with regard to the uterus. The time for the casting off of this membrane was at the menstrual period, a time when this membrane would easily come away, but which could not be removed at any other time without more or less violence. Vessels permeated this dense structure; these vessels were undeveloped; they were unable to accommodate the amount of blood sent there during the menstrual molimen, and this induced distress. The membrane closely adhering to the uterine wall

was not ready to be exfoliated, hence it was a source of distress.

Dr. John Young Brown of St. Louis, Mo., said that his experience in dealing with cases of painful menstruation was that unless there was a palpable pathological condition present, it was better to leave these cases alone. He was opposed to indiscriminate treatment of conditions of this kind. In looking up the etiology of pelvic disease, he had found, in a rather extensive operative experience, that the majority of cases that came to operation were of gonorrhœal infection, puerperal infection, and those cases that came as the result of infection following minor office gynecological procedures. He did not feel that a young woman, who suffered from painful menstruation, should be subjected indiscriminately to operative treatment or even to a gynecological examination.

Dr. L. H. Dunning of Indianapolis, Ind., said that one ought not to approach any case of dysmenorrhœa without studying the surroundings very carefully. He should have a complete and thorough history of the case in order to be able to determine the character of the lesion which was present before undertaking the treatment of the case. He had been surprised in studying the collected histories of some two thousand cases to find that in about 15 per cent. of them there was dysmenorrhœa at the beginning of menstruation. This, he thought, would go to disprove one statement made by the essayist, that nearly all of the cases were due to inflammation, or that most of them were due to gonorrhœal infection or some other kindred infection. In the majority of cases in which dysmenorrhœa began with menstruation, he thought one would find some errors in the development of the organ or errors in the development of the nervous system which would lead to painful menstruation.

Dr. Sellman, in closing the discussion, stated that the object of his paper was to prevent, if possible, this suffering to women, which came on about thirteen times a year. He thought that if any member of the association had to undergo or endure the pain from which some of these patients suffered, even for only six times a year, he would seek some means of relief.

Pseudomembranous Monocystic Tuberculous Peritonitis.—Dr. H. W. Longyear of Detroit, Mich., said that pseudomembranous monocystic tuberculous peritonitis was that form of tuberculous peritonitis which was characterized by the formation of a thick, white, fibrinous pseudomembrane on all of the tuberculous peritoneum, it being found covering the parietal peritoneum and cementing together and covering the intestinal coils in such a manner as to form a sac of greater or less capacity, which contained straw-colored fluid, with occasionally jelly-like masses and shreds floating therein. The author reported three cases of this affection, and stated that the treatment consisted of abdominal section, with evacuation of fluid and the thorough washing out of all shreds and gelatinous masses with decinormal salt solution; thorough drainage by glass or rubber tubes, both abdominal and vaginal. This was to be followed by after-treatment consisting of frequent lavage with a weak aqueous solution of iodine, a drachm to the pint of water, until the pseudomembrane was disintegrated and the purulent discharge that followed had ceased. Internally, the rational treatment of tuberculosis was indicated. The prognosis was bad, although a few cases might recover, if not too far advanced, after months of constant drainage and careful nursing.

Dr. Rufus B. Hall of Cincinnati, Ohio, said he differed from some of the quoted writers in regard to the different varieties of tuberculous peritonitis. He was of the opinion that it was the same disease in different stages of development. In dealing with the operative treatment, ultimate success depended largely upon the variety of the disease, the general condition of the patient, the previous history, the great prostration, etc. Very many of them were in such a condition that they could not withstand much trauma of any kind. His experience in dealing with that variety in which there was no accumulation of fluid had not been very satisfactory from a surgical standpoint. The greatest relief was to be afforded in those cases in which there was an accumulation of cysts, by letting out the fluid and draining. Every one of them should be drained, in his experience. He had, time and again, made section when the patients were in a desperate condition, had put in a drain, and in six months or a year later the patients returned, when he removed one or two infected tubes, and cured them, whereas he thought that if he had done a prolonged operation at the outset, with the patients in a feeble condition, and unable to withstand trauma, they never would have rallied.

Dr. L. H. Dunning said there were two or three questions which ought to be settled in regard to the treatment of cases of encysted tuberculosis of the peritoneum. First, as to whether one ought to remove the Fallopian tubes in all instances. His belief was we should. He believed that all cases of encysted dropsy, when the fluid accumulated in the pelvis, were dependent upon infection of the tube, and it ought to be removed or a fistula would persist indefinitely. It did not require much effort to remove such a tube. These cases ought to be drained through the abdominal wall. They need not be drained through the vagina if one could possibly drain them in the other direction. Should one in these cases attempt to break up the adhesions? Dr. Price had insisted upon breaking up adhesions in all cases of tuberculosis of the intestines. The speaker's belief was that this pseudomembrane was protective, and that one ought not to attempt to separate adhesions.

Dr. Herman E. Hayd of Buffalo, N. Y., believed every case should be treated as a law unto itself. Some need to be drained, others not. Usually those cases with simple effusion or dropsy, which was circumscribed, got well if opened and the opening immediately closed. One did not need to disengage bowel or disturb the adventitious membrane. Simply the entrance of air was an important factor in the cure of these cases.

Dr. J. Henry Carstens of Detroit, Mich., thought that all that was necessary in ordinary simple encysted cases of this condition was to wash them out and let them alone. One should not try to break up adhesions, as serious complications might follow. In tuberculous peritonitis the patients should be let alone as much as possible, and nature given a chance. He said if he operated upon a case of tuberculous appendicitis and drained it, he would get trouble, because along the track of his drainage tube there would be tuberculous deposits, and he would have a fistula there for a long time. On the other hand, if he took out the appendix, closed up the opening with silkworm gut sutures *en masse*, tightly, he would have union without the formation of a fistula.

Dr. D. Tod Gilliam did not believe in too much interference in such cases as had been described. He thought many of these patients would be better without operation. In some cases of encysted tuberculosis, whatever the treatment, the results were likely to be bad. There were other forms of encysted tuberculosis, however, in which one did not have these bad results, and in such cases it was necessary to open up the cysts. He did not believe in breaking up adhesions and separating viscera.

Dr. Longyear, in closing the discussion, said that he had wished to illustrate a rather unusual form of tuberculous peritonitis. Take a case of simple tuberculous peritonitis, with a large cyst, the abdomen full of dropsical fluid, he did not believe it needed to be drained, but agreed with Dr. Hayd that all it was necessary to do was to open it, wash out the cavity, sew up the wound, and the patient would get well. Many of them, however, would have a re-formation of the fluid.

Chronic Adhesive Peritoneal Sclerosis.—Dr. N. Stone Scott of Cleveland, Ohio, said that this was among the rarer abnormal conditions found within the abdomen. It

was progressive, yet was characterized by an absence of active symptoms, including ascites. In the early stages the peritoneum was rigid and contracted; later the connective tissue became excessively hypertrophied, with adhesions between the involved peritoneum and all viscera with which it came in contact. As soon as these adhesions interfered with the functions of any organ, symptoms referable to such interference supervened. When the involvement prevented some important organ from performing its necessary functions, death ensued.

The Relative Value of the Means and Methods Employed in Accouchement Forcé.—Dr. E. Gustav Zinke of Cincinnati, Ohio, read a paper with this title, in which he said that the graduated steel or vulcanite dilators and the ordinary branched or bladed dilators were mainly employed for the purpose of dilating the cervix or os preparatory to digital, manual, and bag dilatation.

The bag or hydrostatic dilators should be employed only when time was not an important element in the case. This form of dilatation was contraindicated in central placenta prævia, and in eclampsia. Deep cervical incisions, or vaginal or abdominal hysterectomy, promised the best results for mother and child. To prevent continuation of the cervical incision, a suture might be placed in the upper angle of the wound. Manual or bimanual dilatation was to be preferred to hydrostatic dilatation when time constituted an important element. Deep cervical incisions and Duhrssen's vaginal hysterotomy were destined to play a permanent and important rôle in the management of forced labors in the future. Many of the cases now subjected to manual or balloon dilatation would be treated by cervical incisions. It was the method of choice in the presence of sepsis of the vagina, because the operation was short in duration and could be performed under a continuous flow of an antiseptic solution. An intact cervix was always an indication for cervical incision. Vaginal hysterotomy was indicated principally when the cervix was the site of malignancy or extensive cicatrization. If there were a palpable difference between passage and passenger, the conservative cæsarean section should be the choice of operation. Metal dilators were very dangerous instruments.

Dr. Henry Schwarz of St. Louis fully agreed with all that Dr. Zinke had said, except that he (Dr. Zinke) appeared to be too radical in some respects. Whenever one made a diagnosis of central placenta prævia, the cervix was so far dilated that no one would think of doing anything except to deliver the child through the natural way. He thought Bossi's metal dilator had a limited sphere of usefulness. He would not condemn the instrument, because he knew it had been used very successfully.

Dr. James F. W. Ross of Toronto, Ont., said he had done cæsarean section three times, with the recovery of the mother in each case, and the loss of the child in each case. The question between cæsarean section and the Porro operation had been pretty well settled, and the conclusion had been reached that the Porro operation, when cæsarean section failed, enabled one to control hemorrhage.

Dr. J. Henry Carstens called attention to the point that many practitioners were too anxious to dilate the cervix in the class of cases under discussion. He had seen them use dilators of all kinds, working around the uterus for two or three days at intervals, and then finally send for someone to help them out of their difficulty. In some cases, after he had been called in consultation, he had found that the women were not in labor at all.

Dr. Eugene J. Brown of Stanford, Ky., said that in these days of aseptic surgery, with the results we were having with mechanical and manual dilatation, cæsarean section would become more popular, and evidently in selected cases more lives to both mother and child would be saved than by other methods.

Dr. M. W. Meyer of Columbia, Mo., spoke of the use of the Bossi dilator, and concluded that one had to go back to the old methods of delivery in cases of placenta prævia, namely, to resort to the use of tampons. One could accomplish more with them than in any other way.

Vaginal Cæsarean Section in Grave Cases of Puerperal Eclampsia.—Dr. J. Henry Carstens of Detroit, Mich., said that mild cases of puerperal convulsions could be controlled by the treatment generally advocated for this class of cases, but there was a grave form of puerperal eclampsia in which one convulsion followed another in quick succession, and the patient finally died. This severe variety of eclampsia could generally be subdued by immediate delivery. This was accomplished usually by manual dilatation or the use of powerful steel instruments, like that of Bossi, but what was better still was the operation called vaginal cæsarean section, which enabled the obstetrician to deliver the woman in about five minutes with little or no danger. He concluded that in grave puerperal eclampsia, as a rule, prompt delivery would save the patients; that manual effort was too slow, and that powerful steel dilators were not always at hand, and often caused serious injuries; but vaginal cæsarean section enabled the obstetrician to quickly and safely deliver the woman.

An Unusual Case with Many of the Symptoms of Appendicitis.—Dr. Magnus A. Tate of Cincinnati, Ohio, narrated this case, which presented an unusual history. The symptoms and history of the case following scarlatinal nephritis led him and others to suppose that probably they were dealing with a case having appendicitis as a complication. The patient urinated regularly and at no time was there a dribbling of urine. The presence of adhesions and the enlarged bladder, with its thick walls, had only problematical causes, not explained satisfactorily by the history of the case.

The patient, a boy, aged seven, was attended by Dr. L. Linss of Cincinnati for scarlet fever, from February 25 to March 18, 1904. On March 21 Dr. Linss was called to see the boy on account of a swelling of feet and hands. On the morning of April 1 all œdema had disappeared; the urine was highly colored, but normal in quantity, with no sugar, albumin, or casts. That afternoon the patient had a chill, vomited, and had pain in the abdomen; the temperature was 99.5°; pulse 90. On April 5 the patient had two more attacks of vomiting; pain in the abdomen was constant, and he had not slept for twenty-four hours; temperature 102°, pulse 130. Dr. Wm. Johnson saw the case with Dr. Linss, and upon examination of the abdomen they found an uneven swelling which extended to the umbilicus, and over the right lumbar region. Upon palpation exquisite tenderness over the appendix was elicited. A diagnosis of appendicitis was made, but further consultation was asked for. The next day Dr. Tate was called. When he saw the patient, six days after the initial vomiting spell and chill, the child had been crying and moaning day and night, and could not sleep; temperature 102°, pulse 132, very irregular; abdomen swollen, especially on the right side, and such marked tenderness that the child screamed if the slightest pressure was made over the region of the appendix. The bowels were constipated and the urine was highly colored. The following day there was no improvement, the pulse was even worse; the temperature remained at 102°. Before putting the child on the operating table, a bed-pan was placed under him and he passed nearly a pint of urine. Chloroform was administered, and an incision was made on the right side two inches in length, over the most prominent portion of the swelling. It revealed a dark-colored sac and a number of adhesions. The incision was lengthened to three inches; some adhesions were broken down with the finger, but a few of them were so firm that they had to be cut. The enlarged opening gave a field of about two inches to work in, and the sac in appearance was not unlike that of a gangrenous bowel. They were at a loss to say exactly what it was, and as adhesions limited the field, gauze was packed about the opening, the child turned to the right side, and a half-inch cut was made into the sac.

A dark green fluid spurted out, which had a strong, heavy odor of stale urine. After the evacuation of about two quarts of fluid, the finger was introduced into the sac, which proved to be the bladder. The opening in the bladder was sewed up, adhesions binding the bladder to the abdominal wall and on the right side to the large and small intestines were broken up, and the enlarged, thick-walled bladder was dropped back into the abdominal cavity. The appendix and appendical region, except for the presence of some adhesions, were normal. An opening was left in the abdomen for gauze drainage, and the rest of the wound was closed. The subsequent history was that the bladder was emptied by means of a retention catheter for forty-eight hours, after that catheterization was practised night and morning for three days. There was a gradual decrease in pulse and temperature, and in seven days both were normal. On the third day a quantity of fluid drained out through the opening, but this gradually ceased, and on April 23, sixteen days after operation, the abdominal wound had closed, and the patient was now in good health.

(To Be Continued.)

INTERNATIONAL CONGRESS OF ARTS AND SCIENCE.

Department of Medicine.

Held in St. Louis, September 20-24, 1904.

(Special Report to the Medical Record.)

OPENING SESSION—TUESDAY, SEPTEMBER 20.

The Modern Conceptions and Methods of Medical Science.—Dr. William T. Councilman of Boston delivered an address with this title at the opening session of the medical division of the congress. An acquaintance with present conditions in medicine and with the literature of the past, he said, had made us aware of a great change both in the conception of medicine and in the methods by which these conceptions were reached. Medicine had been brought into closer accord with other sciences than ever before, and had accepted the methods of science. Its problems were the cause, the nature, the prevention, and the cure of disease. The ontological conception of disease as something differing from and entering into the organism was no longer held, but disease was to be regarded as a condition of living things in which there was a disharmony of function. There were two methods by which knowledge had been sought. In one the endeavor had been made to form conceptions of the objects studied by means of impressions conveyed by the senses. By means of this method an hypothesis might be formed which, tested by observation and by experiment, and found to hold good in all cases under the same conditions, could be used as a basis from which new questions might be formed. The other method was by speculation, a tendency inherent in the nature of man. One of the greatest changes was the general acceptance of the idea that medicine was a natural science and knowledge must be sought by the methods of science, and that disease was the result of injurious conditions acting upon the tissues. The influence of the appreciation of knowledge in medicine was seen by the general acceptance of the idea that the hospital, in addition to caring for the sick, should furnish facilities for the investigation of disease.

A brief review was then given of the more important periods in medical history which began with Hippocrates. The microscope introduced a new era in the study of disease, and the knowledge of the influence of bacteria in disease is due, in the first instance, to the improvement of the microscope, and in the second to the discovery by Koch of methods of cultivation by means of which individual species could be studied. The brilliant results in surgery had changed this from the most despised to the leading branch of medicine. The production of antitoxin was the greatest triumph of scientific medicine, and was due to knowledge obtained by the application of scientific methods to the study of disease. Another great change was in the greater specialization not only in the exercise of medical art, but in investigation, which had brought a great increase in knowledge in different fields. Anatomy and physiology had both become comparative, physiology undertaking the study of the processes taking place in living things, anatomy their form and structure. The unicellular organisms could be studied directly under the microscope, the changes which were produced by injurious conditions and the effects of the changes could be seen. Knowledge derived from such study could be said to be the basis of our conception of inflammation. General medicine had gained by this study a greater knowledge of parasites, their mode of action, and the means by which the organism was protected against them. The study of disease in animals had been directed chiefly to the infectious diseases, and especially to these artificially produced. Diseases were found in animals which were similar to the most obscure diseases in man, and ignorance of these diseases in man was due to their complexity, and the difficulties of investigation. Of recent discoveries in medicine the most striking was that the blood serum contains many complex substances, some of which played an important rôle in the economy; but for others no purpose had yet been discerned, and knowledge of these substances was chiefly confined to their effects. These substances might serve an important rôle by protecting the body against disease, or they might act in the opposite way by providing a means by which injurious substances were brought in contact with the cell. Experimental medicine was comparatively new, and the number of animal species experimented upon had not been large. The opponents of animal experimentation should remember that the greater our knowledge of disease which came in this way the further would disease in man be removed from experiment. There had been in the past a too-wide separation between the public and the medical profession. The public had derived its medical information chiefly through the newspapers, and the information so given had been sensational and unreliable. There was evidence that this is being slowly changed. The successful practice of medicine depended more than ever before upon the use of methods which gave accurate knowledge of the condition of the sick, and training in the exercise of these methods was the most important part of medical education.

SECTION OF PUBLIC HEALTH—WEDNESDAY, SEPTEMBER 21.

The Relation of Public Health Science to Other Sciences.—Prof. Wm. T. Sedgwick of Boston read this paper and said that he used the term public health science advisedly, for any division of human knowledge that had worked out its own laws with strict adherence to the rules of inductive and deductive reasons as public health science had done, and which had reached results which enabled it to predict with accuracy as could now be done in public health science, was entitled to an honorable place among the physical sciences. Public health science had its rise and remarkable development in the eighteenth century; before that time, efforts tending to promote or protect public health being entirely empirical and as often directed to the convenience of mankind as to their safety. In 1767 Sir George Baker made the first scientific discovery in public health science, which happened to be in epidemiology, when he found that the epidemic of colic in Devonshire, England, was due to an obscure poisoning by lead conveyed through the common cider of that district. In 1774, the foundations of state hygiene and sanitation were laid, in consequence of the startling revelations of John Howard, by an act of Parliament providing for the sanitation of jails and prisons. The beginnings of marine hygiene and sanitation appeared in 1776 when Captain Cook was awarded the Copeley medal of the Royal Society for his remarkable success in protecting the lives of his sailors on his second voyage. In 1796 Edward Jenner, who also worked in a strictly scientific manner and employed the

methods of rigid inductive research, laid securely for all time the foundations of personal hygiene and immunization by showing that such modifications of the physiological resistance or susceptibility of the human body could be produced at will so as to make it immune to smallpox. In the eighteenth-century discoveries were the germs of some of the most important divisions of public health science, namely, epidemiology, sanitation, and immunization, and their importance to the public health science of the time and to the development of public health science for all centuries to come was incalculable. In 1802 the beginning of factory hygiene and sanitation was made; in 1829 the first municipal water filter was constructed; in 1834 the discovery of the important relation of poverty to public health, revealed in the famous report of the Poor Law Commissioners; in 1839 the beginnings of registration and accurate statistics; in 1854, for the first time, was clearly taught the lesson, even yet not properly taken to heart, that water may be the ready vehicle of a terrible epidemic of cholera. From 1860 striking epidemics of trichinosis came into public notice, and here, also, belonged the magnificent work of Pasteur; in 1868 Lister, following in the footsteps of Pasteur, revealed the true basis of cleanliness in asepsis; in 1876 bacteriology became firmly established by Koch's studies on anthrax. The decade from 1880 to 1890 could be called the decade of etiology, since then were discovered the hitherto unknown microbes of typhoid fever, tuberculosis, malaria, Asiatic cholera, diphtheria, and tetanus. There was an extraordinary public awakening in England in the middle of the nineteenth century to the importance of sanitation and public health measures, but for some time there was no marked inosculation between public health science and other sciences, such as physics, chemistry, microscopy, bacteriology, climatology, engineering or education. It was not until Pettenkofer and his disciples in Germany, and Angus Smith and others in England, began their splendid chemical work that the tributary stream of sanitary chemistry added materially to that of public health science. The science of architecture, including building construction, heating and ventilation, had done and will continue doing much of importance to the student of public health science. Human beings could live and survive for long periods of time in bad air, but for the best work and the greatest happiness and the largest life, as well as for perfect health, the very best atmosphere was none too good. Hence he believed that the permeability of the walls of houses and other buildings and the heating and ventilation of dwellings, school-houses, churches and other public places, required, and in the near future would receive a much larger share of attention than was given to them to-day. The present had rightly been called the "Golden Age of Engineering," and to no other science to-day, excepting only medicine itself, was public health science more indebted than to engineering science. Compared to the first water filter erected to the water supply of the Chelsea Company of London, in 1829, were the conditions of to-day when nearly the whole of London, Berlin, Paris, Hamburg, and a thousand cities of lesser importance all over the civilized world were to-day protected more or less perfectly from epidemics of typhoid fever, Asiatic cholera and other water-borne diseases by municipal filters, the work of skilful and faithful engineers. Innumerable storage reservoirs and vast distribution systems for supplies of pure water further bore witness to the enormous debt which public health science owed to engineering science, as did also proper street construction and, still more, the splendid systems of sewerage with which so many modern cities were equipped and which served not only to remove quickly the liquid wastes of human and animal life, but kept low and wholesome the ground water, reducing dampness and promoting dryness of environment, thereby apparently strengthening that physiological resistance by means of which the human mechanism fought against the attacks of infectious diseases. The services of the engineer to public health science had not been in any respect more conspicuous than in the application and in the further studies of the principles involved in the processes of water purification. In many cases the introduction of pure water supply had shown a lowered death rate so conspicuous that it was impossible to escape the conclusions (1) that the germs of a greater number of infectious diseases than was formerly supposed were capable of prolonged life in and readily conveyed by public water supplies, and (2) that as a result of the greater purity of the water supply the physiological resistance of the consumers of pure water supplies were enhanced in some manner as yet unknown; the net result being that the general death rate was lowered to such an extent as to lead to a rapid increase of population in communities previously multiplying far less rapidly. Such a diminution in death rate meant a far greater diminution in morbidity rate; in other words, it meant a heightened working efficiency of the population as a whole. And for the most of the results obtained in the scientific purification of water supplied we are indebted to the science of engineering. The reciprocal relations of public health science and the science of education in their beneficial effects upon school children and school-houses had long been emphasized by sanitarians and were sufficiently obvious, but the reverse of the picture was by no means so well understood. The splendid progress that had been made in the last fifty years in public health science as yet seemed to have had little effect upon the curriculum of education. From top to bottom and bottom to top the schools, whether primary, grammar, high, normal, technical, medical, or any other class, wholly neglected any adequate training of their pupils in the principles of public health science, though just now there seemed to be a popular wave of enthusiasm touching the extermination of tuberculosis; but in the United States, both schools and universities were negligent of their most elementary duties in this direction. In regard to bacteriology, he said the bacteria and other forms of plant and animal life had so lately begun to be appreciated that they were still of the greatest importance, and the discoveries of botanists and zoologists and the revelations of microscopists in this domain were comparable in importance to the public health to nothing less than the revelations of the telescope to astronomy. The relation of physiology to public health science was a field ripe for the harvest, but one in which the harvesters were almost altogether wanting. The industrial and commercial age in which we live was characterized by the sedentary life, and the sedentary life was almost unavoidably abnormal, and the problem of maintaining a high degree of resistance became a very serious one; but if the vital resistance of the community in general was lowered then public health was directly and unfavorably affected. In America there were symptoms of a reaction against the evils of a sedentary life in parks being thrown open, public and private gymnasiums, public play-grounds, baths, and other devices for the promotion of personal hygiene, and personal hygiene had a most plain and direct bearing upon the science of public health.

Public Health—Its Present Problems.—Dr. Ernst J. Lederle of New York sent this paper, in which he said the watchword of the new school was sanitary science, and that sanitary science had been the means of calling a new profession into existence, that of the sanitarian. Medical men had been so active in setting forth the importance of sanitary science that it had come to be regarded as the peculiar work of the physician, but the training of the physician did not fit him for administrative offices. A layman was more eminently fitted to accomplish results in public sanitation when working in connection with men skilled in medical knowledge upon purely medical questions. The board of health which would be nearest the ideal was that one which had at its head a skilled physician, one thoroughly schooled in bacteriology, and numbered among its members a competent engineer

who, in the broadest sense of the word, should be a man of affairs, eminent for his administrative ability and knowledge of sanitary science. A national board of health should be established, and this would be a means of accomplishing much. A central body could be resorted to for the settlement of vexed questions such as national quarantine, and direct the training of sanitary officers. The establishment of a national board of health would have the effect of offering suitable inducements to secure men of a higher grade than those who at present enter this field, as men of a higher grade would not take up sanitary science as a specialty unless the work showed sufficient financial returns. The chief business of the board of health was to prevent the spread of contagious diseases, but there had been added many other duties, and one of the greatest responsibilities was to prevent the sanitary service from being corrupted by the evils of partisan politics. When the politician was in control of the sanitary office he controlled all the subordinates, and when that happened the board ceased to be of practical use, and until the sanitary office was taken out from under the control of the politician there could never be any radical improvement in the condition of things. Appointments as sanitary officers should be for life, or during good behavior. The actual work of sanitary inspection was usually done by men who had no theoretical knowledge of the work, and were usually without any training other than a little reading. The laxity of the rules governing the examination of immigrants had resulted in much mischief, the federal government having made no adequate arrangement for the care of sick immigrants. Public schools, it had been truly said, were the foci of contagion, and the rigid medical inspection of schools was therefore a necessity, and a good system would entail extreme care and considerable experience; nevertheless, when the work was carried on by a capable man with thorough experience, the results were manifest. The work to be done in the methods for the prevention of smallpox was still very great and compulsory vaccination should be a requirement to entrance in public schools. While the work done by the bacteriologist had done more than any one thing to prevent the spread of contagious diseases, he believed that private laboratories should be under the direct control of the national board and one function of this body should be the maintenance of laboratories for the manufacture of sera. Better facilities for fighting tuberculosis had been advocated by medical men, and knowledge on this subject had already been increased through efforts to discover a serum for the cure of this disease. Hospitals and sanatoria of large capacity should be provided for the care of tuberculous cases, and the cost of their care and treatment would be small compared with the loss sustained by the community through the loss of their services. Conditions surrounding child labor and the inspection of factories should be carefully regulated. A pure water supply seemed possible only by filtration, and statistics had shown that certain diseases known to result from the use of impure water had decreased, and also that when impure water had been displaced by pure water there was an invariable decrease in certain diseases which had not been suspected of having their origin in the water supply. Coöperation between state and municipal authorities had been productive of much good, and the growing interest in public health problems was one of the auxiliary forces at work for the betterment of conditions. The bacteriologist, the engineer and the sanitarian should work together for the prevention of the spread of contagion, the disposal of waste, and in the solution of a score of other problems.

Dr. Walter Wyman of Washington said there had been recent legislation which provided for the establishment of a national board of health. A number of manufacturers of sera had gone out of business in the past year because they were not willing to have a thorough inspection made of their plants, and others had been unable to obtain a government license until after they had remodeled their methods.

Milk.—Dr. Arthur J. Reynolds, Chicago, in a brief paper on this subject, made a plea for the reduction of time between the production of milk and its consumption. Great improvement had been made in supplying large cities with milk, yet this point had not been fully comprehended, and he had not been able to find one word in literature as to the age of milk. From a dietetic standpoint, milk sold from cans was much less desirable than milk only twelve hours old, and milk thirty-six hours old was not fit for use. Milk became unfit for use many hours before it began to sour. As milk was the only article of diet during the first three or four years of the child, no trouble or expense should be spared to obtain fresh, clean milk, as old milk not only starved but poisoned the young. It cost more to produce clean milk, but it was worth the price, as it meant health and strength for the child. Education was really the important part, for pure, fresh milk, would, be supplied if the public would demand it.

Dust.—Dr. J. N. Hurty, Indianapolis, said that many conditions, such as malaria, rheumatism, "colds," etc., were the result of infection from dust that had accumulated in places where no sunlight could penetrate. Symptoms of coryza had been produced in himself and in a pet dog after having inhaled dust in an attic. He mentioned a case which presented all the symptoms of a "cold" which was relieved when the patient was removed from a dusty atmosphere. The old idea that "colds" were due to excesses, nerve strain, exposure, etc., was incorrect. He had produced symptoms common to "colds" when the factors ordinarily accepted as causing the trouble had not been present. His belief in the theory of dust infection was confirmed by microscopic findings.

SECTION ON PREVENTIVE MEDICINE—WEDNESDAY, SEPTEMBER 21.

The Logical Basis of the Sanitary Policy of Mosquito Reduction.—Prof. Ronald Ross, F.R.S., Liverpool, presented this communciation. He reviewed the work that had been done in the attempt to exterminate mosquitos, and said that no experiments made in this connection had, as yet, proved very satisfactory, owing to the fact that no accurate method had been found for estimating the number of gnats in any given locality. Personal impressions as to the number being large or small might be correct, but this could not be accepted as proof that the number had been really reduced in the absence of any criterion to estimate the actual numbers in figures. The question of mosquito reduction was only part of a larger subject, that of the local reduction of any animal organism. Although all the mosquitos in any given area could not be killed, their propagation could be arrested for as long a time as was desired, provided all breeding places were obliterated, or the larvæ persistently destroyed. The number of gnats, or of any animals, within an area must always be a function of four variables, *i.e.* the birth rate, the death rate, emigration into and immigration out of the country. If such an area be surrounded by a net all gnats within that net would be natives. On the other hand, if propagation is arrested in a certain given area, the gnat population must necessarily consist entirely of emigrants. By the law of probables it was assumed that a very small proportion of mosquitos would travel the limit of migration, but the vast majority would remain in the neighborhood of their birth and die there. The limit of migration was the extreme limit the animal might travel in a straight line during its entire life. A very small proportion would travel that distance in a straight line. The majority would travel back and forth, or in a circle, or at various angles, always remaining not far from the place of birth, and finally die in that neighborhood. By dividing the life of the mosquito into certain arbitrary stages, it was as-

sumed from the calculus of probables that a certain number would reach the extreme limit of migration, proceeding in one direction during all the stages of its existence; a larger number would reach a point somewhat short of the limit of migration, a still larger number reach a point short of that, and so on, until it would be found that the greatest number would be in the neighborhood of the birth-place. If an area of country was then treated, and the propagation of mosquitos arrested in that area, there would be a certain point, the limit of migration of the mosquito, which would be entirely mosquito free, and approaching this mosquito free district there would be a line in which the number of mosquitos would become less and less, until the point of the limit of migration had been reached. If, however, the area thus treated were not large enough, and did not extend beyond the limit of migration, there would always be a number of mosquitos even though propagation was arrested, for there would be emigrants constantly entering the area from without, though the country would be entirely free of native gnats, and the point of greatest density would be near the line of the treated and untreated country, and diminish at an undetermined rate the further advance was made into the no-propagation country until the point of the limit of migration was reached, when the mosquitos would cease altogether. The analysis, imperfect though it was, contained four theorisms; first, mosquito density can be reduced at any point as much as was desired by making the radius of the antipropagation operations large enough. Second, in order to reduce the density at any point to absolute zero, the radius of operations must be greater than the limit of migration. Third, at the boundary of the no-propagation country the mosquito density should be one-half the normal density, provided radius of operations is not less than one-half the limit of migration. Fourth, the effect of the operations will be felt not only within the antipropagation area, but to a distance quite to the limit of migration beyond it.

SECTION ON PEDIATRICS—WEDNESDAY, SEPTEMBER 21.

History of Pediatrics—Its Relation to Other Specialties.—Dr. A. Jacobi of New York presented a paper on this subject. The history of the gradual evolution of pediatrics as a special branch of medicine, and the work of eminent men who labored to this end as well as the literature on the subject, were reviewed. Before 1769 there was no institution specially provided for sick children, but in that year Dr. G. Armstrong established a dispensary in London. In 1784, a similar institution was founded in Vienna by Dr. Marstalier. The first and largest child's hospital in Europe, the Hôpital des Enfants Malades, was founded in 1802. In St. Petersburg the Nicolai Hospital was established in 1834 by Dr. Friedburg, and in 1839 the Poor Children's Hospital in Buda Pesth by Dr. Schopf Merei. Since that time, the increasing interest in the diseases of children on the part of humanitarians and physicians and teachers has multiplied children's hospitals. The United States was the last country to participate in these endeavors. The mostly proprietary medical schools did not find pediatric teaching to their advantage, and it took the hearts and purses of the public a long time to open. The waves of humanitarianism and the demands of science finally overcame previous indolence, and many general hospitals gradually opened special children's wards, while there are pediatric hospitals in all the larger cities. Practical teaching was not extensive, and it took the medical faculties even of universities a long time to appreciate the necessity of special and well-regulated bedside teaching. At the present time, however, there was hardly a great medical school that did not give amphitheater or bedside instruction, either in the children's ward of a general hospital, or in a special children's or baby's hospital. The connection of pediatrics with obstetrical practice was very intimate. Three per cent. of all the mature living fœtuses were not born into post-natal life. To reduce the mortality to that figure it had taken increase of knowledge in the art of obstetrics to such an extent that it had become possible by cæsarean section not only to save the fœtus of a living but also of a dead mother, for the fœtus may survive the dying woman. Not a few were born asphyxiated on account of interrupted circulation, compression of the impacted head or meningeal hemorrhage, which destroyed many in the first week of life, and those who were not so taken away lived only to become paralytic, idiotic, or epileptic. Within a few days after birth microbic infections had been observed from tetanus to hemorrhages, and the intense forms of syphilis. Nephritis was a not uncommon disease of the newly-born and very young, and in many cases was a consequence of what appeared to be a common jaundice, or of uric acid infarction. Otology was mostly a specialty of the young. The newly-born exhibited changes in the middle-ear which were variously attributed to the presence of epithelial detritus, to aspiration of foreign material, or to an œdema occasioned by the separation of formerly adjacent mucous surfaces. Pus was found in the middle ear of 75 per cent. of still-born or dead nurslings. Many of the newly-born that died from unexplained fevers perish from septic material, or its toxins, absorbed in the middle ear, or in the intestines. The great vascularity of the middle ear and the accessibility of the Eustachian tube in the infant, rendered otitis media very frequent. Difficult hearing was very frequent in the young. As early as 1886, Berzold found that of 1,900 children 25 per cent. had only one-third of normal hearing. Whether deaf-mutism was the result of consanguineous marriage could not be definitely asserted. The majority of cases were caused by cerebral or cerebro-spinal inflammation, and many of the congenital and most of the acquired cases were preventable. In dermatology some of the problems should be studied on antenatal and postnatal lines. The congenital absence of small or large parts of the surface was probably due to certain amniotic adhesions, seborrhœa and the mild form of lichen to rapid development in the second half of intrauterine life of the sebaceous follicles. In pemphigus of the palms and soles syphilis was recognized, in eczema constitutional disturbances of the nutrition. A dermatologist who knew no embryology or pedology, or a pediatrist who knew no dermatology, was anything but a competent and trustworthy medical practitioner. The diseases of the muscles interested the pediatrist, the surgical specialist, the orthopedist, the neurologist to an equal extent. Torticollis alone proved that neither the pediatrist, the orthopedist nor the general surgeon could raise the claim of ownership. The relation of pediatrics to forensic medicine was very close. Apparent death of the newly-born and the causes of sudden death in all periods of life had been studied to such an extent as to render negative results of police investigation and of autopsy reports less numerous from year to year. In London there were annually 8,000 inquests, one in fourteen of which were on over-lain infants. In the etiology of sudden deaths the most difficult questions could not be solved except by the facilities furnished by the observations on the young. Forensic medicine had to guard the interests of all, and there was nothing in all medicine more difficult to discover than the cause of death. The best knowledge of the advanced practitioner, of the pathologist, the chemist, the bacteriologist, the obstetrician should be at the service of the people. Every European country understood this and acted upon that knowledge and in this country Massachusetts had broken away from the coroner's institution, which was a fit authority for a backwoods municipality but was so no longer for a cultured people of eighty millions. Now and then even an expert or a body of experts did not succeed in discovering the cause of death. What should be said of a system which now and then did discover the hidden cause of a sudden death? When the New York State Legislature half a year ago passed a bill abolishing the no longer competent office of coroner it was vetoed by the mayor for the reason that the new law was not perfect. It was not pronounced perfect—no law ever was perfect,

but the absurd incompetency and anachronism of the coroner's office was perfect. One of the greatest questions which concerned at the same time the practical statesman, the humanitarian and the pediatrist was that of the excessive mortality of the young. Forty per cent. of the mortality of infants that died before the end of the first year occurred in the first month. This was mostly preventable. Statistics from large obstetrical institutions proved that only 50 per cent. of women were capaple of nursing their offspring for merely a few weeks. What then could be said of the refusal of the physically perfect and well situated women to nurse their infants? He did not speak of 400 but of 400,000 who preferred their ease to their duty, their social functions to their maternal obligations, who hired strangers to nurse their babies, or acted upon their belief in claims of the infant food manufacturers, or were tempted by their own physicians to believe that cow's milk casein and cow's milk fat could be changed into woman's casein and fat, that the live stomach was like a dead laboratory bottle, that the warmth of the human breast and that of a nursing flask were identical. The nursing question was a social and economic one which like so many other problems confronted modern civilization.

Modern therapeutics, both hygienic and medicinal, had gained much by the close observation of what was permitted, or indicated, or required in early age. One of the main indications in infant therapeutics was to fight anæmia which was a constant danger in the diseases of the young. The appreciation of electricity as a remedy had been enhanced by obstetricians, pediatrists, and general practitioners. There was no more powerful remedy for asphyxia and atelectasis than the cautious use of the interrupted or of the broken galvanic current. The domain of preventive therapeutics had expanded with the increased knowledge of the cause of disease, and immunizing, like curative, sera would play a beneficent part from year to year. Among the probabilities of the therapeutical future he counted the prevention of congenital malformations. Knowledge of the physiology and pathology of the nervous system of all ages would be defective without lessons derived from the fœtus and infants. In concluding he said pedology was the science of the young. The young are the makers and the owners of the future and their physical, intellectual and moral condition would decide whether the globe would be more criminal or more righteous. For their education, training and capabilities the pediatrist, as the representative of medical science and art, should become responsible. Medicine was concerned with the new individual before he was born, while he is being born, and after. Heredity and the health of the pregnant mother were the physician's concern. The regulation of labor laws, factory legislation and the prohibition of marriage of epileptics, syphilitics and criminals were his preventive measures to secure a promising progeny. The physician was the legitimate adviser to the judge and the jury, and a seat for him in the councils of the republic was what the people should demand as their right.

SECTION OF PSYCHIATRY—THURSDAY, SEPTEMBER 22.

Relation of Psychiatry to Other Sciences.—Dr. C. L. Dana of New York read this paper. He summarized the things to which psychiatry turned in allied science with expectation of help and coöperation, as follows: Psychiatry turned perhaps first of all to clinical medicine and clinical pathology and physiological chemistry in order to enable it to make complete records and secure the profoundest knowledge of the cases and types of alienation which came under observation, and should form its closest alliance with internal medicine in the broad meaning of that term. As an assistance in such work a sound knowledge of the elementary principles of psychology was needed. Psychiatry expected but little from gross pathological anatomy. It expected a great deal from what might be termed teratological anatomy or a study of congenitally defective conditions not only of the nervous system but of the circulatory and secretory organs. And here again clinical microscopical pathology and chemistry must be associated with the work. Psychiatry as a practical science dealt with administration and custodial care and expected help from the various sciences included under the head of state medicine, and of economics, which worked for a good government and the improvement of the social conditions of a people. Since psychiatry, like all medical sciences, dealt with prevention of disease as well as care and cure, it looked for help to those same sources in procuring the prevention of insanity. Therefore help was expected from the education of the children and of the people—to wise methods of living and especially of marrying; to trying in or out to offset or reduce the effects of increase of urban life, of the use of alcohol and the spread of venereal disease. In the further development of psychiatry help was expected from anthropology and allied sciences, and important relations to law and forensic medicine should continually be held. By these means it was hoped that finally psychiatry would reach that degree of perfection when the increase of the insane would be reduced one-half, *i. e.* to 1 to 600 at least. Then it might be expected that all the insane would be earlier recognized as such and promptly and more effectively treated, so that the percentage of cures would be at least one-third higher. The psychiatrist could then recognize the type of the disease and outline the proper treatment as well as give a rather definite prognosis. The insane who were acutely or curably ill could be properly treated in suitable, easily accessible hospitals, and more serious cases placed in larger and more remotely accessible institutions or private houses, while the hopelessly insane should be cared for in colonies. Finally, there was no more precious thing in a social organization than a sound mind and no more serious hindrance to social progress than a defective one. It was to be hoped that all the sciences which by any means could contribute to interpreting the phenomena of mental disease, to checking its prevalence, and to palliate or cure the suffering of the victims, would feel a special inspiration to secure these ends.

SECTION ON NEUROLOGY—THURSDAY, SEPTEMBER 22.

The Value of Physiological Principle in the Study of Neurology.—Prof. James J. Putnam, Boston, read this paper, and referred to "The Anatomical Principle in the Study of Disease," the title of an address by the late Professor Virchow before the International Congress at Rome in 1894, and pointed out the successes which had been won under this banner of anatomic research. The principle was one that appealed to the faithful plodder and to the man of genius, and its history was the best part of the history of medicine during the past half century. In full recognition of all that had been accomplished there were, however, reasons for the statement that the very successes of the anatomical principle, had thrown unduly into the shadow the claims of another mode of approaching the problem of disease without the aid of which anatomical research must prove inadequate to the task imposed upon it. For this latter principle, which demanded the investigation of the organism as a whole, and saw in disease only a modification of health, the designation of the physiological principle seemed appropriate. The argument was not that the anatomical principle was faulty because it failed to accomplish all that had been hoped for it, as regards the discovery of the essential nature of disease, but that under it the disease process alone was made the object of research, and the mind was turned from the fact that the real object of study should be the organism as a whole seen as readjusting itself to the effects of disease. To make this study was the province of the physiological method of research. There were many conditions where the best insight into the mystery of disease could be obtained by studying the manifestations of life in that form which was called the symptoms of disease, and when this was

done thoroughly the extent of the derangements to which the symptoms pointed was surprising. If these symptoms did not carry the investigator to the heart of the disease they did carry him to the heart of the symptoms. A thorough inventory of the symptoms, that is an inventory of the signs of disordered "functions," would tell even more of what was desired to be known than an inventory of anatomical signs of altered structures. The problem that presented itself most obviously to the physician at the bedside of the patient was the analyzing of a complex group of signs or symptoms, and the more striking part of these symptoms was often due, not to the direct action of anything that could be called a primary lesion, not even to secondary lesions, but rather to efforts on the part of the organism to readjust itself to the new conditions, or internal environment, which both these sets of lesions had created. Two questions suggested themselves; first, what was the significance of symptomatology as a help toward solving the riddle of disease, and, second, did the fact that many symptoms are the signs of "reaction" on the part of the organism, rather than the direct result of any given lesion, disqualify them for the purpose of making a diagnosis and deciding on the proper treatment? The answer to the first question depended largely upon that to the second, and to this he replied that the signs of reaction so far from being disqualified for the purpose of the physician were eminently suited thereto. These signs if properly interpreted through their mode or origin, gave clear information as to the resources of the organism in struggling with the effects. The effects of such a lesion constituted the main part of what was necessary to be known and all that could really be learned, for the disease process considered as independent of these reactions was an abstraction without real existence. Three instances of the overshadowing of the direct effects of a lesion by the process of readjustment were mentioned, namely, myxœdema, the changes which occur at the climacteric epochs of adolescence and menopause, and the extraordinary processes by which the bull is converted into the ox. In all these cases there were two tendencies at work, the one suggesting what might be called disease or failure, the other pointing toward the establishment of a new sort of equilibrium containing well marked elements of stability and health. In no department of pathology was it so difficult to arrive at satisfactory conclusions by the aid of the anatomical method alone as in the department of neural pathology. Anatomical research could hardly touch in any just sense the mental phenomena of daily life where, on the other hand, physiological analysis counted for so much. Those phenomena were of special importance from the fact of their close bearing upon therapeutics. One unfortunate result of too close adherence to the anatomical method was the introduction into medical literature and medical thought the two objectionable terms, "functional" and "organic," because they helped to perpetuate false notions of a physiological, pathological, and clinical sort. Mental action was a real force standing on the same plane with other forces which are familiar, and as such it was capable of influencing the nutrition of the body and only by evasions and subterfuges could be denied the reciprocal relationship between bodily processes and mental states. When a disorder that would be called functional was hostile to the fundamental interests of the organism, it led at once to manifest disorders of nutrition. There was but a difference in degree between the mental operations which favor nutrition and the normal flow of chemical energy and those which interfere with nutrition and hinder the flow of chemical energy.

Isolation Cars.—Owing to the pressure put upon the Pullman Car Company by the United States Public Health and Marine Hospital Service, it is said that the company will run hospital cars on certain days of each week on their California routes, and that consumptives and other sick persons must travel in these cars.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bu eau, Health Department, New York City, for the week ending September 24, 1904:

	Cases.	Deaths.
Measles	42	3
Diphtheria and croup	234	28
Scarlet fever	68	1
Smallpox	4	...
Varicella	11	...
Tuberculosis	307	107
Typhoid fever	84	19
Cerebrospinal meningitis	...	13

Jamaica as a Health Resort.—In the *Journal of Balneology and Climatology* for April, 1904, Dr. E. E. Lewis advocates the claims of Jamaica as a health resort for English people. The tradition attaching to Jamaica as an unhealthy station is rapidly being dissipated, and the pretensions of this beautiful island to be regarded as a health resort are meeting with many advocates. Of a total area of the island more than half is 1,000 feet above sea level. Cool nights, a temperate wind—"the doctor" as it is termed—and an equable climate go far to commend Jamaica to both the sick and the whole. Mineral springs at Bath, some forty-five miles from Kingston, possess the same mineral constituents (but in larger quantities) as those of Aix-la-Chapelle, Bareges and Bagneres de Luchon. —*Journal of Tropical Medicine.*

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 24, 1904.

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Illinois, Chicago	Sept. 10–17	14	2
Louisiana, New Orleans	Sept. 10–17		1(Imported.)
Massachusetts, Lawrence	Sept. 10–17	1	..

PERINEAL PROSTATECTOMY WITH REPORT OF TEN CASES.*

BY HENRY H. MORTON, M. D.,
BROOKLYN, N. Y.

CLINICAL PROFESSOR OF GENITO-URINARY DISEASES IN THE LONG ISLAND COLLEGE HOSPITAL AND GENITO-URINARY SURGEON TO KINGS COUNTY AND LONG ISLAND COLLEGE HOSPITALS AND TO THE POLHEMUS MEMORIAL CLINIC.

MUCH speculation has been exercised and many vague and impossible theories have been advanced, to account for the enlargement of the prostate which takes place in elderly men, but its cause remained entirely unknown until the pathological investigations of Ciechanowski, published in 1900,[1] and of my friends, Drs. Harlow Brooks and R. H. Greene, of New York,[2] showed definitely that all varieties of prostatic hypertrophy are of inflammatory origin. Probably in the majority of instances this inflammation is remotely of gonorrhœal origin.

Pathology.[3]—The pathological change consists in a general enlargement of the entire organ, or the increase in size may be confined to one or both lateral lobes or to the median lobe. The character of the enlargement of the gland and its size and consistency, depend upon which of the normal tissues of the prostate, have been chiefly affected by the process of hypertrophy.

Prostatic hypertrophy occurs in two distinct forms: the *fibroid variety* is due to a hyperplasia of the connective tissue elements of the prostate, which lie between the tubules. The growth and contraction of this tissue results in the compression of the gland tubules, which atrophy in consequence, so that, in the pure fibrous hypertrophy, the gland is transformed into a firm fibroid mass, containing a few glandular elements. This variety is often irregular in shape for the reason that the hyperplasia does not take place equally in all parts of the gland.

It has been asserted that the involuntary muscle fibres in the prostate participate in this form of hypertrophy, but more recent investigations apparently exclude muscular hyperplasia.

The cause of the fibroid form of prostatic hypertrophy is undoubtedly the same as that of connective tissue hyperplasia elsewhere, viz., inflammation. Connective tissue of inflammatory origin, after the acute stages which excite its growth have passed, always contracts as in the formation of a cicatrix. It may happen that a small, hard prostate may in some cases result as a terminal stage of the fibroid form of prostatic hypertrophy, although this form of pure fibrous hypertrophy is exceedingly rare.

The *adenomatous form* is characterized by the presence of round or oval tumors of a semi-elastic consistence which form in the substance of the prostate gland.

In the adenomatous form the epithelial or secreting elements of the gland are involved by the hyperplasia, the result being that greater or less increase in the number and size of the tubules of the gland are occasioned. The connective tissue elements in the pure type of adenomatous hyperplasia are not at all, or but slightly, increased. In this form of prostatic hypertrophy the tubules of the gland frequently become dilated and elongated and are filled with (*a*) the secretion of the cells, which is more or less inspissated, (*b*) proliferating cells derived from the walls of the acini, or (*c*) the detritus resulting from the disintegration of these cells.

The nodules formed may range in size from a pea to a hen's egg, and each may contain many or few acini.

This type of prostatic hypertrophy is induced by inflammation, as is the first-named variety; but in the adenomatous form the inflammation affects primarily the tissues surrounding the excretory ducts and by the compression of these ducts the secretion becomes dammed up within the tubules of the gland, which thus become distended. This is accompanied by an inflammation, which excites the epithelium of the secreting tubules to growth and by the proliferation of these cells, new acini are formed. It is thus evident that while the structure of the tumor resembles that of ordinary adenomata, the etiology and manner of growth exclude it absolutely from the category of new growths.

The cyst-like nodules, formed in the adenomatous type of prostatic hypertrophy, thus originate from the distension and growth of the normal tubules, which have become obstructed and hyperplastic, as the result of inflammation acting as above described.

The nodules may thus consist of a single occluded and distended tubule, with its wall, or of any number of hyperplastic tubules, of greater or less size depending upon their individual distension.

Mixed Type of prostatic hypertrophy is by far the most frequent. In it both the tubules and connective tissue of the normal gland take part in the process, and, as a result, areas of fibrous formation are found, intermingled with enlarged and cystic tubules. Thus the nodules found in this variety consist of both fibroid masses and adenocystic tumors.

Carcinoma not infrequently arises as a complication of the changes described in hypertrophied prostate, as has been shown particularly by Albarran and Halle.

Before looking at the present status of surgery of the prostate it may be of interest to go back and observe its gradual development. The operation of prostatectomy was not evolved in a night, but was a matter of slow growth, each observer adding an increment to the sum total of our knowledge. The

*Read before the Kings County Medical Society.

earliest attempt at operative interference with the prostate was a simple incision, or prostatomy, through the perineum, in which a middle lobe was divided in halves, or a V-shaped piece was cut from the prostate, in order to get a low-level channel from the bladder. It was found that, when the prostate was not more than three inches thick, it was possible to reach a projecting median lobe through an incision in the perineum.

Once within reach, the lobe could be readily divided with a knife, or if it was nipple-shaped, could be nipped off with scissors or an écraseur.

It was, however, found to be rarely possible, by means of a simple prostatomy, to remove a sufficient quantity of the overgrowth of prostatic tissue to relieve the symptoms of obstruction, and the chief advantage which followed was from the prolonged drainage of the bladder, through a perineal tube and the consequent improvement in the cystitis.

In 1888, a great impetus was given to prostatic surgery by two operations of McGill of Leeds, England, who removed portions of the prostate through a suprapubic incision. These growths were chiefly intravesical projections and were removed by cutting with scissors and tearing off with forceps. The suprapubic wound was subsequently utilized for bladder drainage.

In 1890, Belfield of Chicago advanced the technique of prostatectomy by operating through a combination of suprapubic and perineal incisions. In this way readier access was afforded to the prostate and the growths were removed by enucleation, instead of by cutting and tearing. In these operations the prostate was enucleated through the suprapubic wound and the perineal wound was utilized for drainage. The hemorrhage was always considerable and often alarming, and the bleeding could be only controlled by packing, not only the cavity in the prostatic capsule, but the bladder as well.

The mortality of suprapubic prostatectomy remained at a very high rate, in the cases reported reaching 25 per cent., but if all the deaths were known, the death-rate would probably be much higher.

Until this time the prostate had always been removed through an incision in the bladder made above the pubes, but surgeons now began, in an experimental way at first, to utilize again the perineal incision for enucleating and removing prostatic growths.

The practice of making an opening into the bladder above the pubes was still maintained by Alexander, Nicoll, and others, but the opening was used merely for the purpose of introducing two fingers and depressing the prostate so that it could be reached and enucleated from the perineum.

At the present time the feeling among most genito-urinary surgeons is, that the prostate, in most cases, can be removed with more ease and greater safety to the patient's life through a perineal incision and without an opening into the bladder. But it is impossible to practise medicine or surgery on the rigid lines of an unvarying routine, for every case is a law unto itself and unusual conditions demand unusual measures. Occasionally a large vesical calculus or a high degree of intravesical growth, or some other irregularity may require an opening into the bladder, with perhaps complete enucleation through the suprapubic wound. And it is only fair to say that some genito-urinary surgeons—Eugene Fuller, Lilienthal and others, from a long and successful experience with suprapubic prostatectomy, regard it as the operation of choice in every case.

An objection which was urged in the beginning to the removal of the prostate through a perineal incision, was the fact that in many cases the upper border of the prostate was so far removed that it could not be reached by the finger and could not be held immovable while being shelled out of its capsule. This difficulty has been overcome by various mechanical devices, such as Murphy's hooked retractors, Parker Syms' rubber balloon retractor, and Young's prostatic retractors. They are useful instruments, and in practised hands answer the purpose for which they were intended, but in most cases can be dispensed with.

The operation to which the writer would call attention here seems to him the best form of prostatectomy which has yet been presented to the profession. We are indebted for it to the late Dr. Bryson of St. Louis, who did the first operation by this method in 1898.[4] A description of the technique of the operation is briefly as follows:

Technique.—The patient is placed in the lithotomy position and a grooved staff is introduced into the bladder. An external urethrotomy is done, and the knife is carried through the posterior urethra, incising the apex of the prostate.

The forefinger is introduced to explore the prostatic urethra, to note the amount of bulging of the prostate at the sides of the posterior urethra and the presence of an enlarged middle lobe, and also to ascertain if the bladder can be easily reached. The most prominent portion of the prostatic growth which bulges at the side of the posterior urethra is thus found, and the overlying mucous membrane is punctured with the finger-nail or a blunt instrument. The instrument is pushed well into the substance of the gland and on its withdrawal the right forefinger is introduced, tearing its way into the centre of the mass, which is usually quite friable. The finger is then swept around within the capsule of the prostate, shelling out and enucleating the adenomatous tumors, which are grasped and extracted with a lithotomy forceps. The overgrowths on the opposite side of the prostate are then removed in the same way.

The middle lobe still remains to be dealt with; this is accomplished by sweeping the finger from side to side, working up well behind the bladder and pushing the tumor downward. After the growths have been removed by the process of enucleation, the bladder should be thoroughly explored with the finger for a calculus. The oozing which seems to come from the mucous membrane, soons stops after the irrigation of the bladder and wound with hot salt water.

A soft rubber catheter (No. 34 F.) is then introduced through the wound into the bladder for the purpose of drainage, and gauze is firmly packed around it, the pressure absolutely controlling the hemorrhage.

If the field of operation is now examined with the finger, a large cavity will be made out lying immediately below the vesical outlet, which formerly

contained the prostatic tumors and is separated from the rectum only by a thin wall. The floor of the urethra is generally found to be intact, and the mucous membrane forming the sides of the urethra hangs loosely in flaps against the outer sides of the cavity from which the growths have been removed. These flaps in the subsequent healing either slough off and disappear or else become adherent to the walls of the emptied capsule like a skin graft.

In other cases in which the whole prostate has

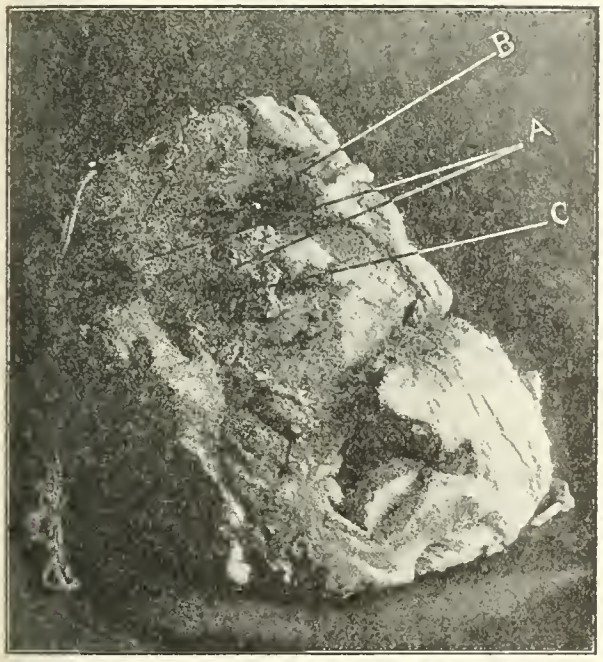

Fig. 1.—Specimen removed post mortem after perineal prostatectomy. A, tags of mucous membrane forming the sides of the posterior urethra; B, bladder; C, cavity within the capsule formerly occupied by the prostate.

been shelled out of the capsule *en masse*, the entire prostatic urethra has disappeared along with the prostate, and the new urethra is formed by a contraction and cicatrization of the walls of the old prostatic capsule.

It was formerly claimed that very large prostates could not be removed through a perineal incision, but it is surprising to find the facility with which enormous glands can be removed from below, provided an assistant will make firm counter pressure upon the abdominal wall just above the pubes with the fingers of the open hand. In nearly every case this is sufficient to bring the prostate within reach. In exceptional cases, however, it may be necessary to make a free incision through the abdominal wall opening up the space of Retzius down to, but not into, the bladder.

The bladder may be pushed down within reach and held firmly by two fingers of an assistant inserted through the incision. (Bryson, 1893; Guiteras, 1901; W. F. Campbell, 1902.)

In exceptional cases, such as a very high grade of intravesical growth, the presence of a large stone, or the escape of a prostatic tumor into the bladder during the process of enucleation, it may be necessary to make a suprabupic opening into the bladder, to facilitate the operation, or to remove a foreign body.

A suprapubic cystotomy is always to be deprecated and should be used only as a last resort, for it increases materially the shock of the operation and causes increased loss of blood. A suprapubic wound is always liable to infection, and the convalescence is materially prolonged from its slow healing; the patient also suffers a good deal of annoyance from the unavoidable soaking of the dressings and bed with urine.

Preliminary Treatment.—Before every operation for the removal of the prostate, it is desirable to give the patient the benefit of a few days' preliminary treatment for the purpose of improving the condition of the bladder and cleaning out the intestinal canal. The patient should be put to bed and calomel, gr. v., administered. A light diet consisting chiefly of milk and abundant quantities of pure spring water as a beverage should be ordered to render the urine bland. Urinary antiseptics may be prescribed for the same purpose.

The cystitis which is always marked in every operative case, should be energetically treated by washing out the bladder. In exceptional cases, when the bladder is very foul and does not clear up under irrigation, a preliminary suprapubic cystotomy, merely for the purpose of drainage has been highly recommended by Bryson.

After Treatment.—The postoperative treatment in prostatectomy requires the closest attention on the part of surgeons and nurses, for the conditions in the first few days after the operation determine whether the patient shall live or die.

Hemorrhage is not to be feared if the wound has been properly packed. Shock may be marked and should be treated in the usual way. Hypostatic pneumonia should be guarded against by making the patient lie on his side and turning him to the opposite side every two hours. To avoid suppression of urine, the patient should drink a tumbler of water every two hours, as soon as he has recovered from the anæsthetic. The bladder should be irrigated with boric acid solution twice every day, and in forty-eight hours the packing in the wound must be removed and the wound repacked, and if a stricture in the anterior urethra was divided, a straight sound should be passed down to the perineal tube. At the end of a week the perineal tube may be taken out permanently and the patient allowed to get out of bed and sit in a chair.

About the tenth day a curved sound (No. 30) should be passed into the bladder, and this must be done two or three times a week until the perineal wound heals. If this precaution is not taken the granulating surfaces in the prostatic urethra are apt to adhere together and the urethra becomes permanently occluded.

While in many cases it may not be necessary, still it is certainly safer for a sound to be passed at occasional intervals during the rest of the patient's life.

Having discussed the technique of the operation of perineal prostectomy at some length, I now beg to present the histories of nine cases of hypertrophied prostate which were operated upon by me, and one case operated upon by Dr. H. E. Fraser in my service at Long Island College Hospital.

Case I. *Hypertrophied Prostate.*—F. B. Finland, tailor. Age 62. Never been sick before present illness. Family history negative. Has had a little trouble in passing water for one year. Went to a physician to have sounds passed, but it was impossible to enter the bladder and the physician made

a false passage in the posterior portion of the prostate. Patient came to hospital immediately, being admitted December 5, 1901. He was suffering from retention of urine and great distention of the bladder. It was impossible to pass any instrument into the bladder, as everything went into

Fig. 2.—Same as Fig. 1; A, cavity within the prostatic capsule formerly occupied by the prostate; B, bladder.

the false passage. External urethrotomy without a guide was done. A finger introduced into the perineal opening showed enormous enlargement of the lateral lobes of the prostate and the entire prostate formed a ring around the vesical orifice. The bladder was drained through a large catheter for three weeks, but complete retention occurred as soon as the catheter was removed, and so it was retained until January 10, when prostatectomy by Alexander's method was performed. A suprapubic opening was made and the perineal wound was utilized for shelling out the prostate from the capsule. There was no hemorrhage and the bladder was drained through a suprapubic and a perineal tube.

January 13.—Bladder has been drained thoroughly through the tubes. The urinary secretion is free, 40 to 60 oz. in 24 hours. The patient showed no signs of shock, and feels well and is free from pain. Temperature ranged from 99° to 101°. Has had a urinary antiseptic with water to drink every two hours; bladder washing was attended to, and the patient was turned from one side to the other every hour. The wounds look healthy. On this date he had a chill and rising temperature to 104°. On January 14 temperature was 96°, but went up again and ranged from 98° to 101° until the man's death. The patient grew weaker, refused nourishment; coarse râles developed over the lungs posteriorly; the urinary secretion was free; the abdominal wound looked sloughing, although the skin had united.

The patient died on January 19.

At the autopsy it was seen that the suprapubic wound was infected, and a sloughing, rotten cavity was found between the skin and the transversalis fascia (caused by sloughing) extending as high as the umbilicus. There was left hypostatic pneumonia (septic) well marked. There was chronic diffuse nephritis with secondary septic infection. The bladder was soft, necrotic, and contracted. The cavity of the capsule of the prostate not much affected, although no signs of repair were evident. The perineal wound was soft and necrotic.

The cause of death was septic absorption, chiefly from the suprapubic wound. Evidences of infection apparent three days after operation.

The patient would probably have recovered if he had not been infected, for although the laceration of the urethra was considerable in extent, the wound looked clean, and the floor of the bladder was intact. The drainage through the perineal tube was perfect and very little urine came in contact with the wound in the prostate.

The mucous membrane at the sides of the prostate urethra, which had been torn loose during the enucleation could be seen as flaps attached at one end and looking healthy. In the event of recovery these would have attached themselves to the sides of the granulating prostatic capsule, thus forming a lining of mucous membrane for the new urethra, or if they had not become attached would have sloughed out. (See Fig. I.)

Case II. *Combined Suprapubic and Perineal Prostatectomy and Removal of a Calculus.*—J. M., ship carpenter. Age 72. About 55 years ago had an attack of gonorrhœa, a few years later another attack, and afterwards chancroids. About twenty years ago he noticed some irritation of the bladder, causing frequent urination; this has increased quite rapidly in the last four or five years, burning, itching and difficult urination being prominent symptoms.

Examination showed a large prostate, moderately soft, about the size of a small lemon. The patient passes about one drachm of urine at a time; the residual urine measures 14 oz., and is very turbid from pus.

Operation was performed January 12, 1903. The urethra was opened on a grooved staff, and a stricture of large caliber in the membranous urethra found and divided. The posterior urethra was dilated with the finger and a calculus was discovered in the bladder. The mucous membrane at the right

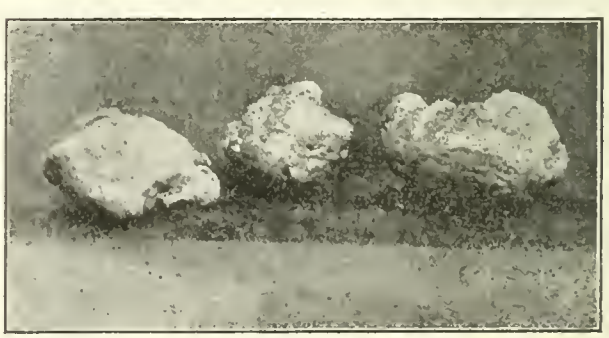

Fig. 3.—Tumor removed by prostatectomy in Case II.

side of the posterior urethra was torn through and two adenomatous tumors were enucleated from the right side with great ease. On the left side the mucous membrane of the posterior urethra was torn through and an attempt was made to enucleate the left lobe; it was partially loosened, but the upper

part was firmly attached to the capsule and out of reach of the finger. The bladder could not be depressed sufficiently from the outside to bring the uppermost part of the prostate, where it was still attached, within reach of the finger, and as it seemed impossible to tear it loose from its attachment to the capsule, I decided to open the bladder by the suprapubic route. I did so for the purpose of (1) depressing the prostate within reach, and (2) removing the stone.

On introducing the finger into the bladder, a very large stone was felt, also the left lobe of prostate, which had been enucleated through perineum, was also found lying loose in bladder, where it had been pushed by previous manipulation, after having been torn loose from its attachments. Some difficulty was experienced in removing the stone through the suprapubic incision, as it was a large one. The abdominal wound was partially closed by suture and Guyon's double tubes were introduced and the bladder was drained through the perineum by a large catheter.

Ten days after the operation, the patient was doing well and sitting up; the suprapubic fistula was still open; but the perineal fistula was about closed.

On March 24 the abdominal and perineal wounds were healed; urine was passed about every three hours, the capacity of the bladder being 4 oz., the residual urine amounting to one ounce; there was no pain on urination. No. 24 F. sound passed easily; the meatus was small and the patient refused to submit to meatotomy. The general condition was good.

Comments.—1. This case shows the importance of always remembering the possibility of the presence of a vesical calculus, and searching the bladder before the operation with a stone searcher, or, when possible, by a cystoscopic examination.

2. In the unmixed adenomatous type of prostatic enlargement the tumors can be shelled out easily through a perineal incision alone, but fibrous tumors (insterstitial fibrous hyperplasia) are so adherent that it may be necessary to make an incision into the bladder, or at least into the space of Retzius, in order to get the prostate within reach and hold it steady enough to enucleate. The various forms of prostatic retractors may often here be used to advantage.

Case III. *Prostatectomy for Enlarged Prostate.*—F. B. age 74, engineer, Belgian. Has always been well and strong except for an attack of dysentery when 19 years old. Has had linguinal hernia for fifteen years, and had gonorrhœa 50 years ago, but never had any stricture. A year ago he began to have difficulty in passing water, which grew steadily worse. Two days ago he had complete retention of urine, which was unrelieved until a catheter was passed and 64 oz. of urine withdrawn, some being left in the bladder. Examination through the rectum showed a large soft prostate as big as a lemon.

Fig. 4.—Tumors removed by prostatectomy in Case III.

Perineal prostatectomy (Bryson's operation) was performed on October 20, 1902. The man was delirious for three or four days after the operation, but little fever and the pulse was good. The bladder was drained with a tube for a week; the urine contained a good deal of blood.

On November 5 the patient was up and on November 10 he could hold his water for three hours at a time. The perineal wound was still open. On November 25, the skin of the scrotum covering the hernia became gangrenous spontaneously and sloughed, but the patient was doing well and perineal wound was nearly closed.

On January 5, 1903, the perineal wound was nearly closed, and the man passed water with perfect ease three or four times a day and once or twice at night.

Case IV. *Enlarged Prostate and Stricture, Prostatectomy.*—B. W., retired sea captain, aged 72 years. He had several attacks of gonorrhœa in youth, but had no trouble in passing water before the present attack, which came on suddenly and without apparent cause on February 27, 1903. The bladder was distended. A guide was passed, but the tunnel catheter would not pass the stricture; a quart of bloody urine flowed away, however, alongside guide, emptying bladder. On February 28, external urethrotomy was performed and a very tight stricture in the membranous urethra divided. A tumor was enucleated from the left lobe of the prostate, but slipped up into the bladder and was extracted with stone forceps. The right lobe of the prostate was not enlarged and the bladder was drained with a catheter (34 F).

After enucleation tumors often escape into the bladder and are difficult to grasp with stone forceps.

The surgeon should always be provided with a lithotomy scoop for their extraction.

After the operation the patient had a chill and rise of temperature to 103°, but the next morning the temperature was normal, and there was no shock. A week later, the patient had tympanites and a rise

Fig. 5.—Tumor removed by prostatectomy in Case IV.

of temperature, which disappeared after a copious evacuation of the bowels.

On April 5 the wound was entirely closed and the man passed all water through penis. On April 24, a perineal fistula which had formed was curetted. On May 22 this fistula was closed. The patient passed water once at night and at normal intervals through day. The patient passed a No. 32 F. sound once in three months. A year after the operation there was no residual urine.

Case V. *Perineal Prostatectomy for Enlarged Prostate.*—John T., age 62, born in Hungary, had gonorrhœa several times in youth. About six and one-half years ago he began to suffer from retention of urine (incomplete). Six months later he had an attack of complete retention for which suprapubic cystotomy was performed in Hungary. Had drainage for two months following. Since then has had to use the catheter two or three times a day. Before coming into hospital he had an attack of retention and could not use the catheter, and in attempting to enter the bladder a physician made a false passage in the lower part of the prostate; he subsequently aspirated bladder and sent the patient to hospital.

Perineal prostatectomy was performed January 26, 1903. A stricture in the membranous urethra was divided by external urethrotomy and the prostatic urethra was dilated with the forefinger, the prostate being found to be very much enlarged. The mucous membrane of the prostatic urethra was torn through and the prostate was enucleated in pieces, the tumors being loosened with the finger and removed with the stone forceps. The abdomen fat and rather tense, nevertheless the prostate was held easily in place during enucleation by pressure above the pubes. The patient had a temperature from 100° to 101° for three or four days after the operation, but by February 2 it was normal. The urine was quite clear and bladder drained perfectly through the tube. The patient was very comfortable and anxious to get up.

On February 13 he had been sitting up for a week. On the attempt being made to pass a sound through the urethra obstruction was noticed, and it was found that the surfaces had united and the posterior urethra was nearly closed; the adhesions were easily broken down with the finger and a No. 30 F. sound was passed into the bladder through the meatus.

On February 21 the patient left the hospital and went home. The perineal wound was closed; the sound passed into bladder readily. The man passed water easily through the meatus, but there was some incontinence at times.

On April 15 he called at my office. He was passing water once or twice at night, but had some incontinence through day and wore a urinal. A No. 30 F sound passed easily. There was 3 oz. of residual urine. Per rectum no enlargement of the prostate was to be felt. I advised catheterization once a day.

Fig. 6.—Tumors, weighing 1,420 grains, enucleated from the prostitute gland in Case V.

Comments.—1. The case shows the practicability of removing the entire prostate without opening the

bladder, even when the gland is enormously enlarged and extends up very high.

2. Forceps is of great use in delivering the pieces after they have been loosened from attachments by the finger.

3. The fact that the lacerated surfaces of the posterior urethra became united during the process of healing shows the necessity of keeping the canal open by the passage of large sounds.

Case VI. *Senile Hypertrophy of Prostate, Bottini Operation, with Prostatectomy Subsequently.*—J. D., æt 67, laborer. Seven years ago trouble began with diminution of strength of the stream and tenesmus in passing water, with several attacks of retention, the last occurring in May, 1899, for which he entered the hospital. There was marked enlargement of both lobes of the prostate, and the cystoscope showed an enlarged middle lobe projecting upwards like a nipple. On May 15 a Bottini operation was performed, three cuts being made posteriorly, interiorly and to the left side. Complete retention was not relieved, and great aggravation of cystitis followed, making necessary an external urethrotomy in order to drain the bladder. Examination with the finger through the perineal incision showed the cuts made by the Bottini knife distinctly. The posterior cut had divided the obstructing posterior lobe of the prostate. Palpitation with the finger in the rectum showed the thickness of the tissues between the rectum and the incision to be about half an inch. The posterior cut gaped open widely enough to admit the finger. The anterior cut was half an inch deep, and also gaped to some extent. The internal vesical orifice was well opened up by the cuts, and the obstruction of the posterior lobe was entirely severed. The bladder was completely destitute of contractile power and could not force out water injected into it with a syringe. The loss of contractile power of bladder appeared to explain the apparent failure of Bottini's operation to relieve the retention, since the operation opened up a free channel for the urine. The bladder was drained for about one month.

On leaving hospital, the patient could pass most of his water through the penis, but retention soon returned, and for the last four years he has had to depend entirely on the catheter to empty the bladder, using it about four times a day. He has been comfortable and able to work, but the Bottini operation failed signally in this case to relieve retention. In June, 1903, he came again into the hospital, saying that since the operation he had worked every day but had to depend on the catheter. About one month ago the urine became very bloody; the bladder was irritable and the patient had to pass the catheter every two hours; the catheter was introduced easily.

On July 2 perineal prostatectomy was performed. The prostate was very difficult to enucleate, being closely adherent to the capsule, and during enucleation a tear into the rectum occurred. The tear was sewed up immediately. The convalescence was uneventful but the opening in the rectum did not heal and the patient left the hospital with a urethrorectal fistula. He went to New York later and the fistula was operated on and closed by Dr. J. P. Tuttle.

Comment.—This case shows the difficulty in enucleating a prostate when Bottini's operation has been done previously.

Case VII. *Prostatectomy.*—A. M., aged 65, farmer, has suffered more or less from retention of urine for the past ten years. Lately he has had a great deal of irritation and almost constant desire to urinate with complete retention. He was treated for three months at the Poughkeepsie Hospital for severe cystitis, and was failing in strength when he entered Long Island College Hospital. His general condition was very poor; atheroma was very marked, the radial artery being like a pipe-stem. There was a beginning bed-sore on the back. The prostate was large and the cystitis was severe.

Perineal prostatectomy was performed by Dr. H. E. Fraser. The wound healed entirely and the patient could take a 32 sound; he passed water a couple of times at night, but had about 8 oz. residual urine for which the regular use of the catheter was advised.

Fig. 7.—Tumors removed by prostatectomy in case VI., four years after a Bottini operation

Comment.—The patient's condition was very unfavorable for any operation, as he had a high grade atheroma, beginning bed-sores, and severe cystitis. Nevertheless he stood the operation well and made a satisfactory recovery.

Case VIII.—*Prostatectomy and Division of Stricture.*—E. R., aged 65 years, ship builder, had gonorrhœa when nineteen years of age with double epididymitis. His general health has always been good. Four years ago he noticed difficulty in passing urine

Fig. 8.—Entire prostate, containing the posterior urethra, removed *en masse* in Case IX.

Two years ago external urethrotomy was done in St. Peter's Hospital, the tube being left in for five weeks. A fistula in the perineum remained open until six weeks before his admission to the Long Island College Hospital, on August 8, 1903. He then had a tight stricture not admitting a catheter. The urine was voided with great difficulty every hour, about half an ounce at a time, with pain and tenesmus. On August 12 external urethrotomy was performed. The deep and anterior strictures were divided and prostate was shelled out through the perineal wound. The bladder was drained. The patient made an uneventful recovery. The temperature never exceeded 99.5° after the operation; the maximum pulse was 80. He was discharged from the hospital one month after the operation.

Case IX. *Enlarged Prostate, Prostatectomy.*—G. B., aged 64, dock superintendent, had always had good health. He had gonorrhœa twice, but no trouble resulted until three years ago, when he began to have a constant desire to urinate with straining. He was catheterized and over one quart of water drawn off. In June, 1902, he consulted me. Examination showed a prostate, 1½ inches in diameter, and a stricture of large calibre. There was complete retention of urine. The patient went on comfortably, using catheter three times a day until November 10, when, retention occurring, a physician was called, who made a false passage and did not get into bladder. I relieved the patient with a guide and tunnelled catheter.

On November 12, 1903, prostatectomy with division of stricture was performed. The entire prostate containing the prostatic urethra was removed *en masse*. Recovery was uneventful. Two months after operation the perineal fistula had healed, a No. 30 F. sound being passed with ease; the residual urine measured one ounce. The man passed water once at night and three time during the day.

Comment.—In this case, although the entire prostate and prostatic urethra were removed, the ejaculatory ducts were evidently uninjured and coitus was satisfactorily performed.

Case X. *Senile Hypertrophy of Prostate, Prostatectomy.*—J. R., æt. 63, a sea captain, was always well and strong. He had had gonorrœha two or three times. Began to have trouble with his water in October, 1903, passing only a small quantity frequently. His condition improved later, and for the last five weeks he had used a catheter three times a day and passed a cupful of water himself at each act of urination.

The prostate was enlarged and soft, 2½ inches in diameter. A No. 24 F sound entered easily; the residual urine was 7 or 8 oz.; the urinary amber, acid, slightly turbid, containing slight trace of alubumin; Urea gr. vi to the ounce, no casts, pus, or blood. On December 19, perineal prostatectomy (Bryson's operation) was performed. A stricture of large calibre was divided in the deep urethra; the lateral lobes of the prostate were removed and the middle lobe was found to be enlarged and prominent, projecting into the bladder like a ball valve; this was also removed and a drainage tube was introduced. Very little hemorrhage occurred and shock was inconsiderable. The patient did well for one week after operation, the bladder being drained well, and blood soon disappeared from the urine. The temperature ranged from 95° to 100°. The secretion of urine was free, about 30 oz. a day.

On December 26 the perineal tube was removed and a sound passed easily into the bladder.

On December 27 the patient had a chill, and the temperature rose to 106°. He had persistent vomiting, feeble pulse, and almost complete suppression of urine. The temperature ranged from 100° to 105° until his death on December 29.

At the autopsy by Dr. Van Cott, a large quantity of orange-gold fat was seen in the abdominal parietes and mesentery. The right heart was dilated and filled with ante-mortem clots, which had been some time in forming. The myocardium contained considerable fat; the valves were all normal. The arteries were generally very atheromatous. The spleen was large and studded with infarcts. The lungs were emphysematous, otherwise normal. Both kidneys were small, with adherent capsule and surface uneven from old cicatrices; the cortex was thin, irregular in thickness, dull, with markings fairly distinct. The liver was quite large and showed signs of marked hypertrophic cirrhosis and fatty degeneration. The prostate gland, previously removed at operation, showed the capsule and operation wound healthy with no evidence of infection. The cause of death was uncertain, probably acute nephritis.

The results in the cases just reported in detail may be summarized as follows: Ten patients operated on, most of them desperate cases and all old men. Two deaths—one from infection of the suprapubic wound, one from acute nephritis ten days after the operation. Two patients obliged to use the catheter subsequently, on account of the residual urine, but both had complete retention before the operation and now can pass water, are not troubled with frequent urination and are perfectly comfortable. One formerly operated by Bottini's method, had a tear into the rectum which was subsequently closed, but had complete restitution of bladder function. The remaining five were entirely relieved and did not require further use of the catheter.

We all know how utterly unreliable statistics are, and we have been misled many times by placing our trust in lying figures. Personally the writer is inclined to accept the honest opinions of men who have had enough experience, so that their views can be crystallized into a definite statement of facts. It is through these facts, which, gathered slowly and with painstaking care, at the cost often of human suffering, and sometimes of life itself, that the arts of medicine and surgery move along in a steady line of advance.

If the writer may then be allowed to express his opinion on the operation of perineal prostatectomy as done by Bryson, he would summarize its advantages as follows:

1. The comparatively low death rate.

2. The rapidity, ease and facility with which the prostate can be enucleated.

3. The trifling amount of hemorrhage and shock.

4. The excellent bladder drainage and ability to keep the patient's bed and dressings dry.

5. The rapid convalescence, the patient getting out of bed within ten days.

6. The complete restitution of the bladder functions in most cases.

HOSPITAL NOTES ON EPIDEMIC CEREBROSPINAL MENINGITIS.

BY JOSÉ M. FERRER, M. D.,
NEW YORK.

VISITING PHYSICIAN TO ST. VINCENT'S HOSPITAL AND THE FRENCH HOSPITAL.

THE following notes are offered as a contribution to the history of the epidemic of 1904:

During the Spring and Summer there were admitted to St. Vincent's Hospital twenty cases of epidemic cerebrospinal meningitis. Two entered in March, five in April, nine in May, two in June, and two in August.

The cases appeared after an exceptionally severe winter, marked by the great prevalence and mortality of pneumonia.

The patients all came from the tenements. Eight were Italians, ten from the United States, one from England and one from Ireland. Twelve were males and eight females. Three were married and seventeen single. Nineteen were whites; one was a negro. There were more adults than children. The ages ranged from 3 to 39 years, as follows: 3, 5, 7, 7, 10, 11, 14, 16 17, 18, 20, 21, 23, 24, 24, 25, 28, 29, 34 and 39.

Of the twenty patients, ten died (50 per cent.): One on the day of admission, one on the day after, two in 2 days, two in 3 days, one in 5 days, one in 29 days, one in 34 days and one in 105 days.

Of the eight Italians, six died (five males and one female). Of the ten from the United States, three died (females). The English woman also died. In all five males and five females succumbed.

The cases did not materially vary from the classical course so often described. Eleven were long cases; nine were short. The duration of the long cases that died were, as nearly as could be ascertained, as follows: One (K. F.) 14 weeks, one (P. P.) 12 weeks, and one (T. D.) over 4 weeks. The long cases that recovered lasted as follows: One (M. McC.) 13 weeks, one (W. B.) 7 weeks, one (A. L.) 6 weeks, one (F. J.) 5 weeks, two (G. C. and D. Q.) 4 weeks, one (J. C.) 3 weeks and one (J. P.) about 3 weeks.

Of the short cases that ended in recovery one (G. H.) lasted 3 days and one (A. McK.) about 2 weeks. Of the short cases that died, one (E. H.) lasted 2 days, two (L. C. and J. F.) were ill 3 days, two (F. C. and F. P.) 4 days, one (M. McC.) 6 days and one (S. B.) 7 days.

There was some variation in the types of the disease. No fulminant cases were met with. Sixteen of the cases, though of varying duration, might be classified as of the ordinary type. One was of the marantic type, one of the intermittent type, one of the abortive type, and one of the chronic type.

The symptoms noted might be analyzed as follows: All the patients had pain in the head—severe as a rule. All had more or less fever. All had some degree of retraction of the head and rigidity of the neck. All had delirium of varying intensity at some time. All had more or less leucocytosis. Constipation was the rule, except in two patients, who had early diarrhœa. Seventeen had vomiting at some time—most of them at the beginning. Fifteen had general hyperæsthesia. In fifteen Kernig's sign was elicited. Twelve had initial chills. Three had chills late in the disease. Fourteen had stupor, off and on. Eleven developed coma. In one instance the coma lasted ten days before death. Twelve had general rigidity of the body. One had clonic spasms of the face. Ten had opisthotonos. Seven had the typical eruption. Nine had herpes labialis. Two had rose spots. Five had convulsions. Five had strabismus. Six had earache, deafness and slight discharge.

Complications: In two cases broncho pneumonia was noted. In two congestion of the kidneys. In one double parotitis. In one vascular keratitis. In four there was marked pain in the joints and limbs, though no true arthritis was noted.

The following sequelæ were noted: In one paralysis of limbs. In one atrophy and partial blindness of one eye. In one deaf-mutism and idiocy. In six deafness.

Lumbar puncture was done in eleven cases. In four of these the culture was positive; in seven negative.

In the treatment, the following were employed: Ice bags, sponging, laxatives, enemata, morphine, potassium bromide, potassium iodide, ergot, quinine, Warburg's tincture, sodium salicylate, strychnine sulphate, digitalis, whiskey, fluid diet followed as quickly as possible by light diet.

Appended are short reports of six of the cases:

Ordinary type; fatal case; complicating parotitis; autopsy.—S. B., an Italian flower maker, 18 years old, single. In the United States six months. Admitted to my wards May 26, brought thither by ambulance.

It was difficult to obtain a history of his family, previous health and habits, as neither he nor his friends spoke English. He was said to have had malaria in Italy recently. He had had no severe previous illness.

His present attack began suddenly two days ago with intense pain in the head which later extended to the nape of the neck. On the day of invasion he had two severe chills which were attributed by him to his malaria. He had marked nausea and frequent vomiting, which continued most of the second day. There was much thirst and the fever seemed high. The pain in the head and neck increased and he became delirious at times. No eye or ear symptoms were noted. The bowels had moved.

The second day of the disease his neck became very stiff, the head was retracted and drawn to the left side. His headache and fever continued and he grew worse.

On admission to the hospital, the third day of the disease, his temperature was 104 1-5°, pulse 90 and respirations 44. He looked very ill. The head was retracted and drawn to the left. The entire body would become rigid on attempts to move him, and he would complain of pain. There was general hyperæsthesia. Kernig's sign was elicited.

On rounds he seemed mentally clear for the time being and told me of his two chills, of his vomiting, of his malaria and wanted to know if he was dan-

gerously ill. It was noticed that he had spasmodic twitchings of the face, especially in the superciliary region. His pupils were evenly dilated. About his shoulders, chest, back and arms and slightly on the face was found the typical eruption. This consisted of petechiæ—some of them of considerable size, dark colored and not disappearing on pressure. They seemed not so much hæmorrhagic as pigmentary at this time. Several blue spots (purpuric) were seen on the lips. An examination of the blood was negative as to parasites. The white count was 32,400. The urine was amber, acid, specific gravity 1024 and contained a heavy trace of albumen, a few granular casts, many red and white blood corpuscles and urea gr. viii. to ℥i. His heart and lungs were normal. The spleen could not be felt. Abdomen negative. He was ordered a sponge bath, an enema, ice bags to the head and spine, milk diet, quinine sulphate gr. x t.i.d. and potassium bromide gr. xx every five hours.

May 27th.—Delirious and restless, retraction of head and stiffness of neck; general rigidity and hyperæsthesia. Complains of his headache. No eye or ear symptoms. The temperature this day ranged between 103.6° and 101.8°. Towards night it rose to 103°. His pluse remained all day around 90, and his respirations around 30. There was no vomiting. Bowels moved. Eruption and blue spots on lips still present.

May 28th.—On rounds I found him in a restraining jacket violently delirious. Dilated pupils. Marked rigidity and retraction of head. Retention of urine and had to be catheterized. The range of temperature was higher than the day previous, varying between 104.6° and 103°. His pulse increased very much in frequency, running between 120 and 100. The respirations were a little less, between 24 and 28. This day he grew markedly worse. In the afternoon, within a few hours, he developed an intense parotitis on both sides, which swelled his face enormously. By 9 p. m. his temperature was 104.6°, pulse 140, and respiration 22. Lead and opium wash was applied cold. He could not open his mouth well and there was sordes. Efforts were made to keep the mouth clean with a disinfecting mouth wash. The quinine was stopped, as it did not seem to have any beneficial effect. The bromide was continued, and it was found necessary to give a hypodermic of Magendie ♏ vi. An enema was given. The patient was sponged. The ice bags were continued and ℥vj of milk were given every three hours.

May 29th.—The delirium, rigidity and other symptoms persist. There is now slight strabismus. The parotitis is very marked and interferes with proper feeding. The temperature this day ranged between 104 and 103. The pulse between 120 and 116. The respirations ran between 24 and 28. A hypodermic of Magendie (♏ vi) gave him three hours' rest. The bromide is continued, ice bags, enema; milk increased to every two hours.

May 30th.—Had slept four hours in the night, but his general condition is worse. Stupor alternates with delirium. There is progressive weakness. The face is bloated from the parotitis. The lips are puffed out and have still the ecchimotic spots. Eruption persists. Blood examination negative as to Widal's reaction. The white blood count to-day is 27,000. There is no anasarca. Incontinence of urine has set in. The temperature this day ran between 104° and 103°. The pulse was between 122 and 118. The respirations increased from 26 to 44. He commenced to have dyspnœa and slight cough. Numerous small moist râles were heard over both sides of the chest and other signs of pulmonary œdema developed. At 1 p. m. his temperature had reached 106.4°, his pulse was 150 and respirations 46. Towards evening he became comatose.

May 31st.—Moribund. Unable to swallow. Coma. His temperature dropped slightly. His pulse was 150 and respirations 52. He died at 2:40 P. M.

Autopsy, 10 a. m., June 1st, by Dr. John Howland. Body of a small, fairly well nourished adult, with small amount of fat. Surface: Eruption present on shoulders and back. Purplish spots on lips. Parotids enlarged but no pus found. Pleuræ normal. Lungs ædematous. Beginning broncho-pneumonia, areas of which are small, deeply congested and elevated above the surrounding lung tissue. Bronchial glands enlarged, red and pigmented. Pericardium normal. Heart: left ventricle contracted, right ventricle dilated. Valves, normal. Kidneys, slight congestion. Cortex, somewhat swollen and cloudy. Spleen, very small and soft. Stomach and intestines, normal. Liver, surface smooth, size normal, cross section shows slight nutmeg markings. Brain, vessels of pia much congested and around a few of the larger vessels leading up from the base there is a small amount of exudation. Convolutions flattened and the whole brain seems increased in size. There is a fibro-purulent exudate on the base, beginning just behind the optic commissure and covering the interpeduncular space, the inferior surface of the pons, medulla and that portion of the cerebellum lying closest to the medulla and extending also to a slight extent over the superior surface of the cerebellum.

The ventricles contain only a slight amount of free fluid. The lateral ventricles are filled with very turbid fluid and the walls are covered with purulent exudate which is thickest upon the choroid plexus. There are small punctate hæmorrhages just beneath the ependyma, which is granular. The third ventricle is dilated and also the fourth, which has small hæmorrhages, and also a purulent exudate. The cord could not be examined. A stained smear showed the presence of the diplococcus intracellularis meningitidis.

This patient died on the seventh day of the disease (five days after admission). An interesting feature of the case was the complicating parotitis. Radcliffe, Tourdes, Jenks and Hirsch mention it as a rare complication. Stillé met with only four or five cases.

Ordinary Type: Recovery.—J. C., a girl singer, 11 years old, born in the United States. Admitted by ambulance on May 11th.

Nothing of importance was elicited as to the family history or as to the habits of the child, except that she was actively engaged in the theatrical profession as a singer.

This morning upon awaking she complained of severe pain in the front and back part of the head. She felt so ill that she ate no breakfast. In the afternoon she vomited twice, first the contents of the stomach and then a greenish fluid. The headache continued with increasing intensity throughout the day, the child grew worse, seemed very feverish and was restless. At 7:30 p. m. she had violent convulsions lasting about three-quarters of an hour, followed by marked stupor, in which condition she was taken to the hospital at 9:30 p. m. and was assigned to my service.

On admission her temperature was 103.4°, pulse 116 and respirations 28. Well nourished child. Great restlessness and delirium. She does not an- 116, and respirations 28. Well nourished child.

head. Head retracted and pulled over to the left side. Rigidity of the neck. General hyperæsthesia, the slightest movement causing the child to moan in pain and to become rigid. The pupils are even and dilated. They do not react well to light. Nose and mouth seemed normal. Lungs negative. Heart rapid, but the sounds were normal. Abdomen slightly retracted. Spleen not palpable. No typical eruption found, but a large patch of herpes was on the left upper lip and cheek. Legs were drawn up on thighs. Kernig's sign obtained. Reflexes did not seem exaggerated. An examination of the blood was negative as to Widal and parasites. There was moderate leucocytosis. The urine showed a heavy trace of albumin and was about normal in quantity.

During the next two or three days the retraction of the head became more exaggerated, so that it amounted to opisthotonos and the rigidity of the neck and body generally was increased. The child could be moved as if her body was made of one solid piece or as if she were a statue, while she pleaded to be let alone. She remained in a semi-stupid condition, lying on her side in dread of the slightest movement which would increase her pain. The stupor alternated with delirium. The fever was high, though irregular. During the succeeding days the acute manifestations of the disease varied considerably. The fever would abate for a day and then unexpectedly rise again to 104. The delirium would cease for a time, giving place to refreshing sleep, only to recur perhaps the next day for hours. The bowels remained constipated and had to be attended to daily. Ice bags, bromide of potassium, iodide of potassium, morphine, sponging, and fluid diet besides laxatives and enemata were employed.

Very gradually the spasmodic manifestations subsided, and the child commenced to ask for food, which was given her. The headache persisted for weeks. The emaciation was marked. The herpes labialis seemed slow in healing. There were no complications. Soon the symptoms all became ameliorated. In a week the delirium ceased and the child rested well. The retraction, spasm and hyperæsthesia disappeared more slowly. The temperature occasionally rose without warning, and again dropped to almost normal for days at a time.

Improvement continuing, the child was allowed to sit up a little at the end of two weeks. Regular diet was given. She left the hospital at the end of a month somewhat emaciated and pale, but perfectly well, no sequelæ remaining.

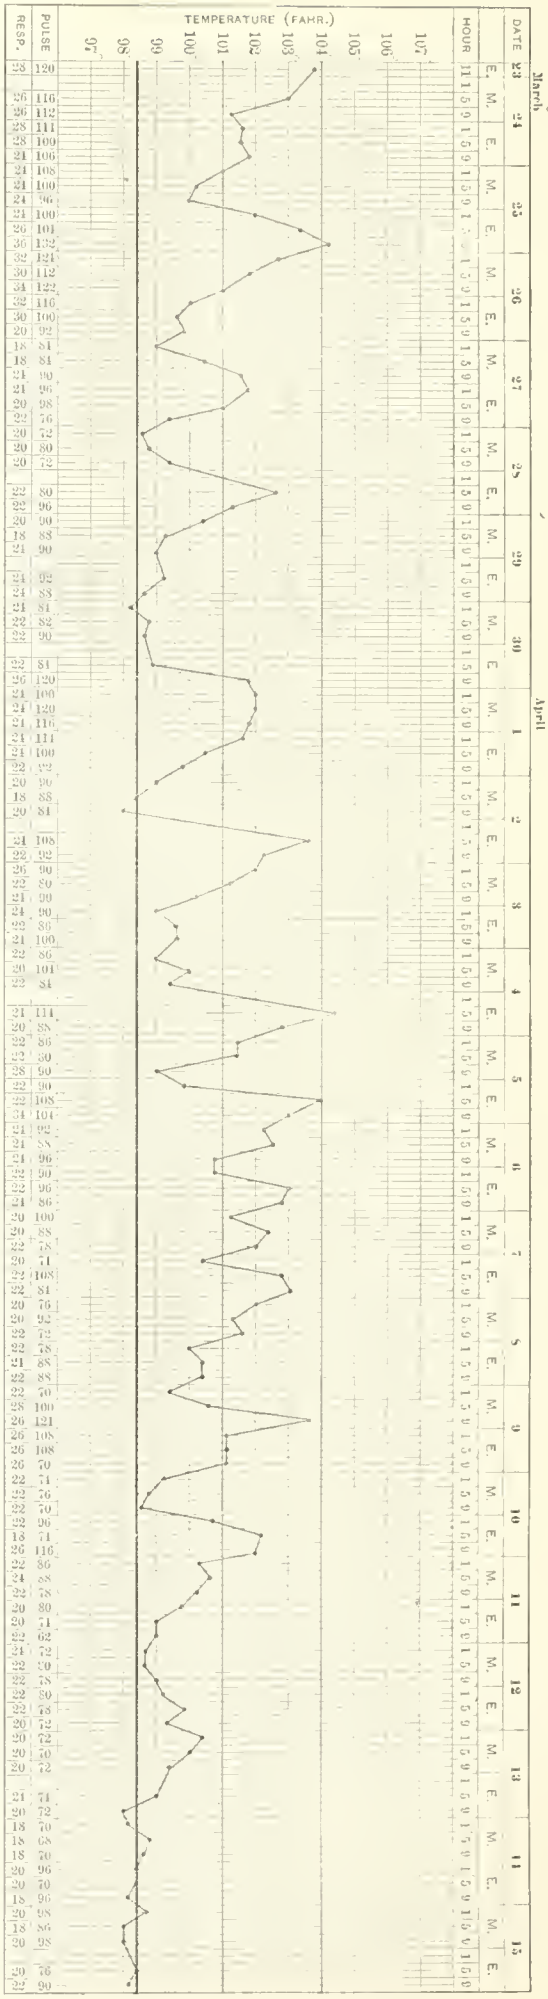
Intermittent Type: Recovery.—G. C., a married Italian laborer, 25 years old, who landed in this country nine days ago. Brought to the hospital by ambulance on April 23. (See chart.)

Impossible to obtain family history, previous history or account of his habits, as he does not speak English.

His present illness began three days ago with headache, which soon became very intense. This was accompanied by loss of appetite, marked nausea and vomiting of stomach contents and bile, without any blood. The pain in the head seemed at first confined to the frontal region, but later extended to the nucha and down the spine. There was a great deal of fever.

On the second day his neck became very stiff, and the head was pulled back and somewhat to the left. There was great pain when an attempt was made to move the head. The entire body was stiff and sore. He became worse and his friends brought him to the hospital.

On admission his temperature was 103.8°, pulse



120 and respirations 28. The patient is a fairly nourished but thin adult. He is slightly delirious. The skin is warm and moist. There are marked retraction and spasmodic contraction of the neck muscles causing inability to move the head forward or from side to side without great pain. The pupils are dilated and fixed; no reaction to light and apparent loss of accommodation; no strabismus. Hearing seems defective. The nose is apparently normal; no discharge. The tongue is red, dry and coated. The heart and lungs are normal. The abdomen is very much retracted; not tender. The edge of the spleen can just be made out. Kernig's sign can be elicited; the reflexes are present, but slow. There is general hyperæsthesia. The patient looks very ill. The urine is cloudy, of amber color, acid, specific gravity 1,020, contains a trace of albumin, no sugar; no casts, some débris.

He was ordered calomel and soda, to be followed by magnesium sulphate; milk diet, ice bags to head and spine. Later, Magendie, ♏ vi. with atropine 1-100 gr. hypodermically.

April 24th.—Slept fairly well. To-day he is delirious off and on. There is retention of urine and has to be catheterized. Examination of the blood was negative as to parasites. The white blood count was 26,200. Magendie, ♏ vi given.

April 25th.—Sleeping most of the day. Catheter still has to be used. High fever. A slight papular eruption (rose spots) is noticed on the shoulders and back. He has marked labial herpes. Taches cerebrales. Low cry at times. Very drowsy. White blood count 22,000. A lumbar puncture was done. Clear fluid, negative. Subsequently a culture was without result. He was put on fluid extract of ergot ♏ xx t.i.d., ice bags, sponging, milk, Magendie's solution.

April 26th.—Slept greater part of the night. The temperature through the day had a marked drop—from 104.2° to 99°.

April 27th.—Temperature rose again to nearly 102°. Same treatment.

April 28th.—The patient is brighter this morning. Passes urine normally. His temperature was 98.5°. By 5 p. m. it had again risen to nearly 103°. There were periods of stupor.

April 29th.—He is passing about 33 ounces of urine in 24 hours. It is cloudy and has a trace of albumin. No casts. The temperature gradually fell to normal and remained so for nearly two days. Meanwhile the retraction of the head and rigidity of the neck and body continued and he complained bitterly of the pain in the head.

May 1st.—The temperature has again gone up to 102°, gradually dropping to normal towards evening. Light diet allowed. Constipation. Ergot continued.

May 2d.—Calomel. Enema—large result. The temperature in the morning was 98.5°; by 5 p. m. it was close to 104°.

May 4th.—Temperature 99° in the morning. In the early afternoon he had a severe chill, lasting fifteen minutes, and by 5 p. m. his temperature was was 104.4°. Headache very severe. Retraction of head again marked. Delirium has returned. Moans from time to time. Examination of the blood negative as to plasmodia. No pus collection discovered anywhere. Ergot stopped. Ordered quinine sulphate gr. x night and morning.

May 5th.—Temperature at 9 a. m. was 99°. At 3 p. m. he had another severe chill, lasting about a quarter of an hour, and by 5 p. m. the temperature had risen to 104°. Patient complained of pain in the left ear, and there was a slight discharge of serum, which continued for a few days. The ear was syringed every three hours. The quinine was increased to gr. x t.i.d., and gr. x of bromide was added to each dose. The pain in the head was very severe. During the next few days the temperature was quite irregular, but did not go below 100°. His general condition was about the same. Retraction, rigidity and headache continued. Is now eating better. He is still constipated.

May 7th.—White blood count 13,800. No plasmodia. Slight anæmia. Quinine was stopped and ʒij of Warburg's tincture t.i.d. was ordered.

May 9th.—In the early morning his temperature was 99°, but a chill lasting ten minutes occurred, and by 9 a. m it had gone up to nearly 104°.

Next morning (May 10) the temperature was 98.5°. Towards evening it went up to 102°. Complains of the pain in the head.

May 11th.—The retraction and stiffness are far less marked than they were. The temperature gradually dropped to normal, but there was an evening rise. There is great languor. Emaciation is noticeable. Complains of his head. Eyes were examined by Dr. Peter Callan and found normal. Blood showed slight loss of hæmoglobin and polymorphonuclear leucocytosis. The Warburg's tincture was stopped. He was put on iodide of potassium gr. x t.i.d.

May 13th.—Resting quietly. Vomited twice. Headache still continues. The temperature dropped from 100.4° to 98.5°, and did not rise again.

May 14th.—Very dull and sluggish. Passes his urine involuntarily. Considerable prostration. His iodide of potass. was stopped. Ordered strychnine sulphate, gr. 1-60 every four hours. To-day his left eye is red, the cornea dull and slightly inflamed (vascular keratitis). This subsided in a week. The patient is eating well. The retraction and stiffness gradually disappeared. He continued to improve, and on May 21 he sat up for an hour. He was put on mistura amara and given full diet. Convalescence was slow but uninterrupted, and by May 22 he was up and about the ward.

The feature of interest in this case was the intermittency of the fever and other symptoms. His temperature chart is subjoined. His chills, remissions of fever, the absence of fever for a couple of days at a time, etc., reminded one of malaria, but no organisms were found, and quinine and Warburg's tincture did not influence the course of the disease. Again, at times it reminded one of a septic or of a pyæmic case, but no cause could be found beyond his meningitis. I have thought it fair to class this case as of the intermittent type, so often described. The disease lasted about four weeks.

Marantic Type; Recovery.—M. McC., a girl 3 years old, born in the United States, was admitted to the hospital on April 14. Her mother was admitted at the same time, ill of cerebrospinal meningitis, from which she died the following day. There were eleven children in the family. Eight of these have died from various causes. This child has had no previous diseases.

The grandmother states that the child had a fall about two or three weeks ago, since which time her left arm has been stiff. She was well until Sunday (April 10), when she had a severe attack of vomiting and diarrhœa. She had a high fever, and seemed to have great pain in the head. For the next two days she was restless and unable to sleep. Her fever continued, and the vomiting and purging persisted. She was raving and had a high-pitched cry. Her

neck became stiff, the head was drawn back, the whole body was rigid, and she became cross-eyed. There were no convulsions.

On admission her temperature was 102.2°, but rose towards evening, and next morning was 104°. Her pulse was 120 and her respirations 30.

The child is poorly nourished. She lies on her side, with legs drawn up and the whole body rigid, so that she can be moved like a statue or as if she were made of one solid piece. The head is markedly retracted and the neck stiff. She is very hyperæsthetic, the slightest touch or effort to examine her eliciting whines and cries of pain. There is pronounced strabismus, the defect seeming to be in the left eye. Heart and lungs were normal. The abdomen is markedly retracted. The spleen cannot be felt. Nose and mouth normal. Hearing not impaired. There is no evidence of paralysis of limbs. Kernig's sign present. There is no eruption. The urine was negative. White blood count 32,000.

During the night she was restless, delirious and noisy. Her temperature rose to 104°. Diarrhœa continued, but the vomiting had ceased.

For the next few days she lay in about the same condition—rigid, hyperæsthetic, with high fever, her delirium giving place to spells of marked stupor. It was difficult to feed her. The diarrhœa soon ceased.

In the course of the next two weeks she was very ill, her temperature being irregular and ranging from 105° to 100°; her pulse very rapid, from 140 to 110; her respirations from 42 to 22. Emaciation had become pronounced, her features pinched, her skin pale, sallow and loose on her bones. She remained motionless a large part of the time, and whined when moved. The retraction amounted to opisthotonos. The strabismus did not improve, and sight in her left eye seemed impaired. She had labial herpes. After rigidity had somewhat subsided her limbs hung limp and useless, but there seemed to be no real paralysis. She grew much weaker and refused her nourishment. The picture was one of marasmus. A disastrous termination seemed inevitable. But she lingered on. After a few days of improvement she again became worse with fever, delirium and rigidity as before. But at last her temperature dropped; very gradually she commenced to eat a little more. She received daily inunctions of oil and cocoa butter. She was given syrup of the iodide of iron ℥j t.i.d., and later a tonic of citrate of iron. She took cod liver oil.

Her rigidity and retraction yielded after a time. Imperceptibly she commenced to improve, and today, while still extremely emaciated, pale and limp, so that she does not move her limbs to any extent, with diminished vision of the left eye, the entire orbit of which seems atrophied and sunken, cross-eyed and pinched looking, it may be said that she is convalescing. Her mind is clear. She answers and understands. She eats better. She has gained a little flesh, and it is confidently expected that she will entirely recover, though but a wreck of her former self. The disease has lasted thus far three months and a few days.

It is worthy of comment that both her mother and herself were brought to the hospital suffering from cerebrospinal meningitis. The former died on the day after admission. Was the child infected by the mother, or was the causative environment operative in both simultaneously? It was impossible to determine. The child sickened, however, after the mother. The duration of the disease is also interesting, for at the end of three months she cannot be said to be entirely well. The type of the disease was of that marantic character which was met with in at least two other cases at the hospital.

The sequelæ of strabismus, atrophy and partial loss of sight of the left eye, and some loss of power in the limbs, particularly the legs, are noteworthy.

And, finally, the fact of recovery itself seemed remarkable, when her desperate condition for weeks warranted a positive fatal prognosis.

Chronic Type; Congenital Hydrocephalus; Paralysis of Arm and Leg; Strabismus; Deaf-mutism; Idiocy; Death.—P. P., an Italian boy, 10 years of age. In the United States a year and a half. Admitted to my service on May 23. An incomplete history was obtained from the mother through an interpreter. The boy's parents, brothers and sisters are alive and healthy. At birth the child had a very large head, which increased in size gradually. He commenced to walk at nine months. Mother says he was always active and in good health. He attended school, where he seemed as bright as the other boys.

His present illness commenced suddenly, two months ago. He then had a severe chill, lasting some time, followed by fever, nausea and vomiting. He then complained of terrible pain in the head and in the back of the neck. In a short time he became delirious, and would cry out at times. Later, the mother noticed that his head was much drawn back and that he looked cross-eyed.

About two days after the invasion the boy's chest and back were covered with hemorrhagic spots. The fever continued; the symptoms already described persisted; he was unable to talk or recognize people, and he gradually lost power of the left arm and left leg. His mental state grew worse. During the two months he lost a great deal of flesh and strength. There were periods when he seemed slightly better, but he would soon have recrudescences of the disease. He was able throughout to retain his nourishment and ate fairly well.

On admission his temperature was 98°, pulse 120, respirations 26. The child is of normal length, but his head seems out of proportion, and measures 22 inches in its greatest circumference. There is marked emaciation, all the bony framework being visible. The skin is pale and sallow.

The head is markedly retracted and pulled to the left. The muscles of the neck and spine are rigid, and the head cannot be moved without causing pain. The eyes seem always fixed and gazing to the left. The pupils are even, but dilated widely, and they do not react to light. There is well marked strabismus. There is evident loss of hearing. There is no discharge from the nose. The mouth seems slightly drawn to the left. The abdomen is very much retracted. Spleen not felt. Liver normal. The action of the heart is rapid, but no abnormal sounds present. Examination of the lungs is negative. The left arm is paralyzed, the hand being drawn up and contracted. He can use his right arm, and keeps it constantly in motion with a swaying movement. If a piece of bread is put in this hand he will carry it

to the mouth and eat it. The left leg is paralyzed and contracted. He cannot draw it up, but the knee jerk is exaggerated and there is slight plantar reflex. The right leg seems normal. The knee and plantar reflexes are very much increased.

The boy is deaf and dumb. His mentality is nil. He cannot at all be roused to his surroundings. He recognizes no one, not even his mother. He passes his feces and urine in the bed without notice. He continues to eat whatever is given to him. The urine is amber colored, acid, specific gravity 1018. There is a slight trace of albumin, no sugar, a few epithelial cells. The white blood count is 17,200.

For the following two weeks he lay in bed without any practical change in his condition—leading a purely vegetative life, without speaking or hearing, soiling the bed, eating whatever was given him, occasionally becoming very restless and agitating his right arm, sometimes being noisy inarticulately, the rigidity of the neck and head and the strabismus persisting. The range of temperature was never high.

Two weeks after admission there seemed to be a recrudescence of the disease, with higher temperature, intervals of stupor and intensification of his other symptoms. After a few days the temperature dropped and the disease resumed the chronic course which had characterized it. Afterwards the temperature never rose above 100° until shortly before his death. The pulse kept between 90 and 100; the respirations between 20 and 24.

His emaciation increased. He gradually became weaker, and died at 5 p. m. on June 21. The disease lasted three months. It was impossible to obtain an autopsy.

The interest of the case centers in the fact that the cerebrospinal meningitis occurred in a child with congenital hydrocephalus; also in the paralytic manifestations, strabismus, deaf-mutism, and idiocy remaining.

Abortive Case.—G. H., a schoolboy, 7 years of age. Admitted by ambulance on May 3. Has had measles and whooping cough, but has been in good health otherwise. For a couple of days he has not seemed well, but severe symptoms did not develop until last night. He then had a convulsion, followed by intense nausea and vomiting (stomach contents, bile and mucus). He had a high fever and complained of terrible pain in the head, down the back of the neck and along the spine.

To-day the fever continued, and the mother noticed that his head was pulled back and a little to the side, that there was rigidity of the neck and body, and that it seemed to hurt him when attempts were made to move his head or change his position. No eye symptoms were noticed. The bowels were rather loose. Micturition seemed normal. The child grew very restless and at times was delirious. The doctor who saw him before being brought to the hospital treated him with ice bags to the head and back of the neck.

On admission his temperature was 104.8°, his pulse 118, and his respirations 36. He is well nourished, but looks very ill. The skin is normal. He has opisthotonos. The neck is very rigid and painful, especially when attempts are made to flex or rotate the head. There is general rigidity of the body and general hyperæsthesia. The child lies on his side moaning and in active delirium. There is slight dilatation of the pupils, whch react slowly to light. The ears are normal. There is no discharge nor other abnormality in the nose or mouth. The tongue is red, moist and coated. The heart and lungs are normal. The abdomen is slightly retracted; spleen not palpable; liver normal. The boy lies with his knees drawn up, and the limbs seem stiff. Kernig's sign present. Reflexes slow. The white blood count was 15,000.

A dose of castor oil was administered and an enema was given later, producing a good result. A general sponging with cold water was followed by ice bags to the head and spine. A milk diet was ordered.

He was very restless all night and very noisy. The following day, in addition to the other measures employed, he was put on iodide of potassium gr. v t.i.d.

The pain in the head was still very severe, but the opisthotonos was less marked. Delirium had ceased, and the child slept a good deal. The temperature was high, but irregular. By midnight of the 5th it had dropped to 99.4°, and never rose again. The next morning there was marked general improvement, and he made a rapid recovery, leaving the hospital perfectly well on May 11.

What seemed like a desperate case, ushered in with a convulsion and vomiting, marked by high fever, opisthotonos, general rigidity of neck and body, noisy delirium, intense headache, leucocytosis and the appearance of a grave illness—cleared up completely in a short time—the entire attack lasting but three days.

441 Park Ave.

EARLY CIRRHOSIS OF THE LIVER AND ITS TREATMENT.

By HUBERT RICHARDSON, M.D.,

BALTIMORE, MD.

LATE PATHOLOGIST TO MOUNT HOPE RETREAT; DEMONSTRATOR OF PHYSIOLOGICAL CHEMISTRY, UNIVERSITY OF MARYLAND; PATHOLOGIST TO THE MARYLAND HOME FOR FEEBLE-MINDED CHILDREN.

Cirrhosis of the liver is a disease of wide and varied interest to both the clinician and the pathologist from its frequency and from the symptoms which it may produce. Out of 500 autopsies at the Johns Hopkins Hospital, advanced cirrhosis was the direct or accessory cause of death in 49 cases, or practically 10 per cent. In Berlin, Förster found cirrhosis of the liver in 31 cases out of 3,200 autopsies, or about one per cent., and in Kiel, Lange found interstitial hepatitis in 56 out of 3,100 autopsies, or about 2 per cent. These statistics do not cover the mild or beginning cases, which are very numerous, few autopsies failing to show a certain amount of hepatitis, proving that the disease is an adjunct with many and varied conditions, which, from the importance of the liver to the economy of the system, must be reckoned with in general treatment.

Atrophic cirrhosis of the liver is associated with chronic interstitial nephritis, with cardiac insufficiency with and without renal complications, and arterial cirrhosis without either cardiac or renal disease, which points to the hepatic loss of function, with consequent failure to destroy toxins and to imperfect metabolism, being a factor in their produc-

tion. Mayer, Wickham, Charcot and Gomboult and others have shown that obliteration of the bile ducts will produce cirrhosis, the failure of the excretion of the bile producing an hepatic toxæmia. Alcohol has been accused of producing hepatic cirrhosis, but it is probable, as shown by Boix, that it is not the alcohol, but the organic toxins produced in the perverted digestive processes. Boix's results have been confirmed by the experiments of Welch and Friedenwald. Boix obtained true cirrhosis from the administration of butyric acid, of lactic, and of acetic acids. On the administration of the above organic acids, together with alcohol, he obtained a cirrhosis, but not so marked as when no alcohol was given, which would seem to show that alcohol in small quantities retarded the cirrhotic formation. Extract of fæces, the bacillus coli and its toxins produced no cirrhosis. The cause of cirrhosis, as far as experimental evidence goes, is the absorption of toxins from the intestinal tract formed in perverted digestion and the reduction in the outflow of bile, preventing the elimination of the toxins from the liver. Syphilis and malaria are also causes which, though not due to intestinal intoxication, are toxæmias; they produce excessive hæmoglobin destruction, increasing the amount of bilirubin formed, which, if not eliminated by the bile, remains in the circulation, producing the icteroid discoloration of the skin and acting as a toxin.

The early manifestations of hepatic cirrhosis prior to the formation of structural changes which can be recognized by physical examination are very indefinite; in fact, they are the same as may be produced by congestion. It must be remembered that cirrhosis of the liver occurs in the young, and may be congenital, in middle life and in old age, in the abstemious, in the glutton, in the alcoholic and in the teetotaler, and that its manifestations are often paroxysmal in character; that it may be associated with general decline of health, icteroid discoloration of the skin, feeling of weight or vague discomfort in the hypochondrium, loss of or capricious appetite, irregularity of the bowels, the evacuations showing perhaps occasionally a deficiency of bile, a broad, flabby-coated tongue, a foul breath, loss of weight, a muddy, leaden complexion, with a permanent dilatation of the cutaneous capillaries, a true telangiectasia in various parts of the body, especially in the face. This telangiectasia is of great diagnostic value. Such a group of symptoms as the above, when combined with irritability of temper, mental depression, insomnia, mental slowness, with various nervous symptoms, the result of the toxæmia, are strong evidences of commencing cirrhosis and hepatic insufficiency, while a history of alcoholism, excessive appetite, long standing indigestion and constipation prove that whatever other organs may be implicated the liver functions are deranged. Certain physical signs are also often present in the very early stages, such as distention of the abdominal veins, hemorrhoids and tympanites of the abdomen. The above symptoms are what could theoretically be expected from hepatic insufficiency, and though cirrhosis may not be the cause of the liver incompetence, it is probable that it will be a result if the incompetency becomes chronic. The urine often gives considerable confirmatory evidence, the presence of bile pigments in the urine in small amounts is suggestive; the excess of ammonia nitrogen the result of acidosis, as well as excess of uric acid and residual nitrogen are pointers; but the diagnosis of hepatic disease in the clinical laboratory has not yet proved very satisfactory; analysis of the bile, if it were possible, would give valuable information.

The functions of the liver, in spite of an enormous amount of work, are as yet but very imperfectly understood. They can be briefly summarized as having to do with the metabolism and storing of the various food substances. It also probably both forms and destroys uric acid. It is the seat of the most energetic oxidative processes of the body, which are of many kinds and due to many varieties of oxidative ferments, producing tyrosin, leucin, hexon bases and other advanced products of proteid digestion. While the above processes occur in various other organs to a less extent and less actively, the liver has the unique function of forming and excreting bile, a function which is closely connected with the physiologic action of the organ, and also with the intestinal digestion and absorption of fats.

Bile, when injected into the circulation, is toxic, four to six c.c. per kilo of animal causes death in convulsions. The coloring matters are responsible for two-thirds of the toxicity, as bile filtered through animal charcoal loses this amount of its toxicity.

The bile salts have a powerful cytolitic action, but they are never found in normal blood. (Crofton claims to have found them in normal blood, but in very minute quantities.) With the bile are eliminated many of the mineral poisons which have been arrested by the liver, as well as some other products of proteid decomposition.

The free flow of bile into the intestine is of great importance to the functional power of the liver, as well as to the digestion of fats and the peristalsis of the intestines. Although the bile is not germicidal, putrifying easily outside the body, in the intestine it seems to inhibit the growth of bacteria, as has been shown by the increased elimination of indol and ethereal sulphates in the urine, when the quantity of bile is decreased, and by their decrease on the administration of sodium glycocholate.

The active principles of the bile are the bile salts, tauro- and glycocholate of sodium. They hold the cholesterine and bilirubin in solution and prevent the formation of gallstones and also when given by the mouth will dissolve stones in situ. Being reabsorbed from the intestine, they are cumulative when administered, and may, if given over a long period, produce burning, loose movements of the bowels. As has been mentioned, bilirubin is toxic, and it is of importance that its elimination should be accelerated, which can only be accomplished by increasing the flow of bile. As yet no chologogue has been found except bile salts; the drugs mentioned as having this action in the pharmacopœia have time and again been shown to have no such action.

Poisons circulating in the blood cause a change in normal bile increasing its visicosity, agglutinating the walls of the bile ducts, obstructing their lumen and causing retention of bile and stagnation of the liver processes. Under such conditions, the pigments are forced into the circulation, giving the icteroid discoloration of the skin which is seen in plumbism, malaria, typhoid fever, syphilis, phos-

phorous poisoning, and many other diseases, the result of a toxæmia.

Gallstones appear to be the result of inflammation of the gall-bladder, which causes a reduction in the quantity of bile acids secreted. Austin found in three cases of biliary fistula, after operation for stone, that the bile contained only a very small proportion of cholalic acid to cholesterin; under normal conditions human bile, according to Hammerstein, contains twelve to thirteen times as much cholalic acid as cholesterin. Austin found in his cases that the amount of cholalic acid was only one-eighth of the cholesterin. Evidently the absence of bile acids is connected with the formation of gallstones.

Vaughan Harley and Wakelin Barratt inserted large cholesterin gallstones into the gall-bladders of healthy dogs without producing inflammation, and found that in from six to twelve months they were completely dissolved, but when cholecystitis was induced at the time of the introduction of the stones, no solution took place, proving that the absence of the bile salts caused by the inflammation prevented the solution of stones, and it would seem to follow that the administration of the bile salts will not only prevent the formation, but dissolve stones already present.

Hepatic cirrhosis is the result of a toxæmia and its treatment must therefore consist in the removal of the cause of the intoxication, with, at the same time, stimulation of the liver so that it may do its part in the oxidation and elimination of the poisonous substances. Attention to gastrointestinal digestion is of the first importance, as, if the food supply of the organism is perverted or reduced, it cannot be expected to recuperate. The elimination of bile from the liver should be increased by the administration of sodium glycocholate with the addition of small doses of mercury. The fluidity of the bile can be increased by the administration of alkaline mineral waters with sodium salicylate, which latter drug seems to have some influence in increasing the fluidity of the bile. Biniodide of mercury with iodide of potassium has a very beneficial effect in many cases of nephritis, which are associated with hepatic insufficiency. Prof. Black, of Edinburgh, called attention to this method of treatment some years ago.

As toxæmia enters so largely into the etiology of nearly all diseases, and as the silver is the organ upon which devolves the duty of extracting, oxidizing and eliminating the toxins, it is evident that in all diseases hepatic efficiency should be promoted, an important factor of which is a free elimination of bile.

CASE OF STRANGULATED UMBILICAL HERNIA WITH UNUSUAL FEATURES.*

By J. J. BUCHANAN, M. D.,
PITTSBURG, PA.
SURGEON TO MERCY HOSPITAL.

The patient presented for examination was admitted to the Mercy Hospital at noon, July 6, 1903. She was a married woman, aged 48 years, weighing 240 pounds, and had been the subject of a large umbilical hernia for seven years, irreducible for a year or more. Twenty-six hours before her admission to the hospital symptoms of strangulation had appeared, namely, colicky pain, vomiting, prostration, obstipation, and induration of the hernial mass.

The condition on admission was one of great prostration. The pulse was 116 and of small volume. Implanted on the abdominal surface was an immense umbilical hernia, extremely tense and with gangrenous skin covering the greater part of its area.

First Operation.—This was performed at 1 o'clock in the afternoon of July 6. The serious nature of the condition having been explained to the patient, her consent and co-operation were gained for an operation without anæsthesia. For several years it has been the writer's custom to perform operations for strangulated hernia without general anæsthesia, and especially in cases of strangulated umbilical hernia, in which, in the presence of vomiting, anæsthesia is particularly fatal. Disinfecton of the abdominal wall was accomplished, and to a degree also of the gangrenous coverings of the sac. A perpendicular incision was made over the whole extent of the hernia and the contents—gangrenous intestine and omentum—burst into view. In opening the hernial sac a small incision was made into the gangrenous bowel, and so great was the tension of the contents that the gas rushed out with a noise like the crack of a pistol, and fecal matter shot out to a distance of several feet. Through this opening most of the matter within the gangrenous bowel was removed by expression, and the opening was then temporarily closed with a ligature. The sac and its contents were then washed and examined. The entire mass of intestine, which was so large as to simulate the bulk of the gastro-intestinal tract, was in a state of complete gangrene. Incisions were made in the median line, both above and below, which freely divided the hernial ring. Traction was made on the gangrenous contents in an effort to deliver the adjoining portions of bowel, but without avail, as all had already come out that the mesentery would permit. Around the base of the mass, at the

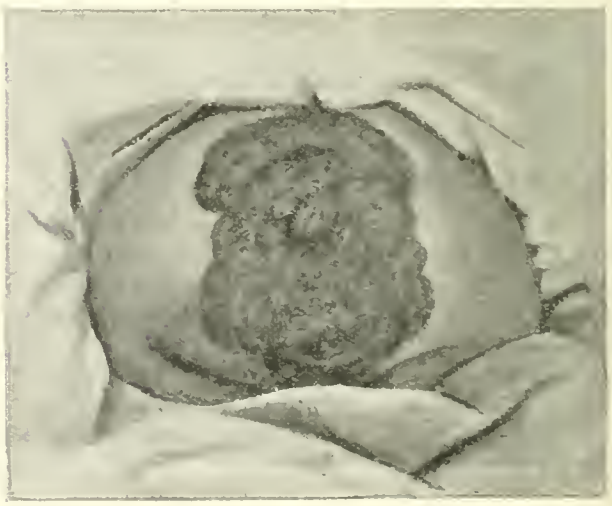


FIG. 1.

position of the enlarged ring, was packed a large quantity of iodoform gauze, for the purpose of protecting the peritoneal cavity from contamination by the discharges from the gangrenous intestine and its fecal contents until nature should have walled it off with plastic lymph. The surface was then cov-

* Paper read at a meeting of the Allegheny County Medical Society.

ered with a voluminous gauze dressing, and the patient was sent to bed with practically no expectation of her recovery.

Contrary to all anticipations, she began at once to improve. At no time did she exhibit any sign of peritonitis from leakage. Vomiting ceased, and

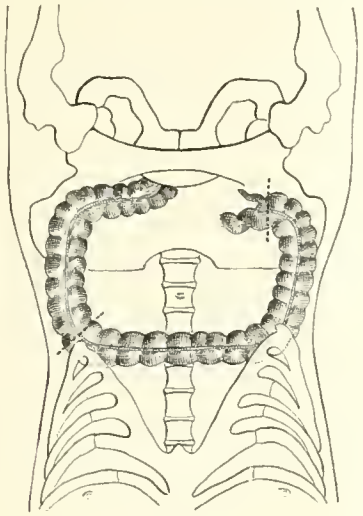

FIG. 2

such portions of the abdomen as remained accessible were soft to the touch. On the second day the gangrenous intestines were opened at numerous points for the evacuation of the contents, and on the third and subsequent days were irrigated with a catheter passed inside the lumen through the openings. It was soon evident that fresh fecal matter was being washed out and that we had now a condition of artificial anus.

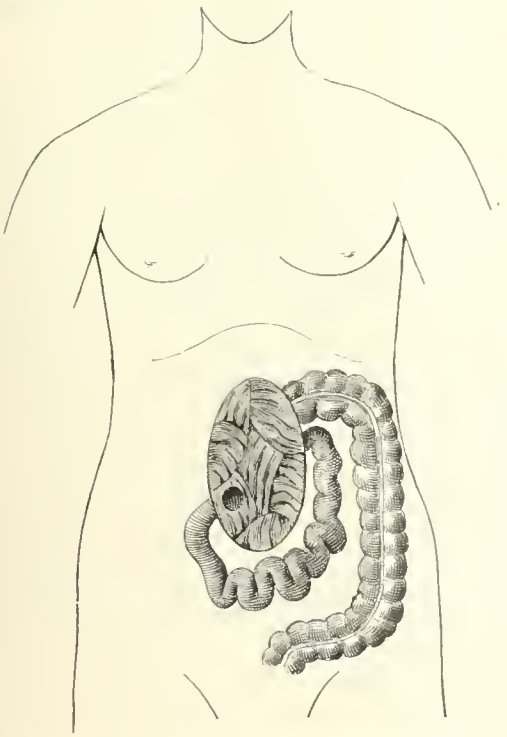

FIG. 3.

At the expiration of a week the gangrenous mass, though collapsed, was still attached, and a photograph, of which the accompanying drawing is a reproduction, was taken (Fig. I). A few days later the bulk of the mass was cut away; through a misunderstanding the specimen was destroyed before measurement. The remaining shreds were removed as they separated, leaving a large, deep granulating pit below and the protruding mucous membrane of bowel above. Examination showed that the mesenteric portion of a part of the bowel remained, due to the fact that the mesocæcum and the mesocolon of the splenic flexure were too short to permit the passage of the entire caecum and splenic flexure through the ring, and that the line of mortification had passed through the wall of those parts of the bowel longitudinally, leaving the distal part alive and its mucous membrane forming the surface of the mass protruding from the ring. It was then to be seen that the projecting artificial anus was small intestine, and that its lumen was continuous with the spread-out surface of the remains of a portion of large intestine. It was therefore the ileocaecal valve; and the destroyed intestine had been the free surface of the caecum, the ascending and transverse colon, with the distal border of the splenic flexure (Figs. 2 and 3). It was now evident that an intestinal anastomosis would restore the continuity of the alimentary tract.

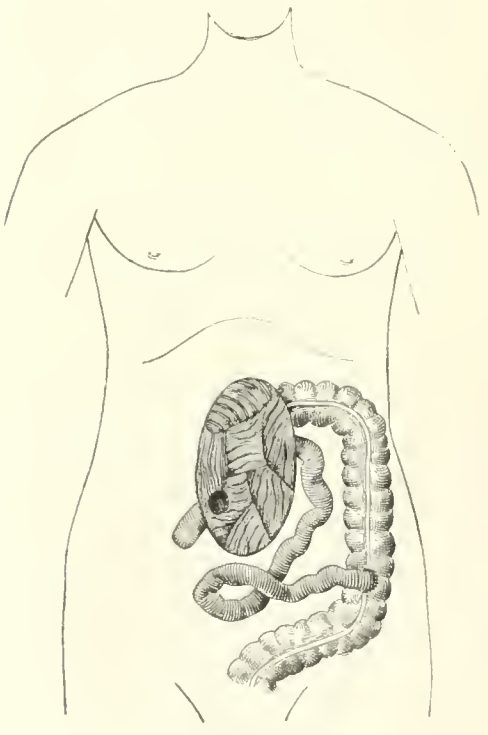

FIG. 4

Second Operation.—This was performed on August 24. Prior to operation a solid, flexible bougie was passed about six inches into the ileum through the artificial anus, and the protruding collar was tied firmly about it. This procedure served two necessary purposes; it prevented the escape of fæces during the operation, and it identified the lower end of the ileum from the peritoneal side. Thorough washing of the exposed mucous surface was followed by covering it with a dry aseptic dressing, which was stitched to the skin to prevent shifting. This allowed the performance of a median laparotomy entirely below the defect, and with an aseptic field. Under ether anæsthesia the abdomen was opened in this location and the lower end of the ileum, containing the bougie, was brought to the surface. The bougie was then withdrawn somewhat and the ileum was severed transversely between clamps at the low-

est practicable point. The distal portion, containing the bougie, was then closed with two rows of silk sutures. The sigmoid flexure of the colon was then brought into the wound and an incision made into its side corresponding to the size of the cut end of small intestine. The cut end of the ileum was then implanted into the opening in the side of the sigmoid (Fig. 4) by simple continuous suture, and the abdomen closed.

The patient made a normal recovery, and since the operation the bowels have moved by the natural channel. She was dismissed from the hospital on September 27, with directions to return later for obliteration of the surface of mucous membrane, which was about four inches in breadth by six in length.

Third Operation.—This was performed on October 23, and consisted in dissecting off the mucous and submucous coats and burying the remaining raw surfaces with layer sutures of catgut. This procedure was carried out without anæsthesia, and gave but little pain. About three-fourths of the exposed mucous surface was removed. The remaining fourth yet remains, and will be removed in the same way at the first time convenient for the patient. It is interesting to note the peristaltic action of the portion of bowel exposed and the alternate wrinkling and smoothing of its mucous surface.

A CASE OF SUPPOSED PRIMARY TUBERCULOSIS OF THE PHARYNGEAL TONSIL.

By DONALD M. BARSTOW, M.D.,
NEW YORK.
ASSISTANT SURGEON, N. Y. EYE AND EAR INFIRMARY; SURGEON, NEW AMSTERDAM EYE AND EAR HOSPITAL, ETC.

Mr. C. V., 29 years old, married, a native of this country, was sent to my office by Dr. John F. Russell, of this city, on the 14th of last January. He gave the following history:

His mother and father are both living. He has one sister, aged 24, who is in good health. There are no cases of tuberculosis in his family connection. He has always been well up to about two years ago. Since then he has suffered with cough. For a time last summer he had pain in his chest, fever and nightsweats. These same symptoms have troubled him from time to time ever since. For the last three or four months he has suffered from "a continuous bad cold in the head," with snuffling and a great deal of expectoration. About a month ago he raised some blood, and his attending physician found that his sputum contained tubercle bacilli. The doctor also said that there were signs of tuberculosis in his chest. He was advised to give up his position and go to the southwest. On January 13 he consulted Dr. Russell, who, being unable to find any signs of disease in his chest, and thinking that the trouble might be located somewhere in the upper air passages, referred him to me.

Examination of the nose revealed a deviation of the septum to the left side, with a spur formation upon it, not sufficient to obstruct the nostril completely. Posterior rhinoscopy revealed the presence of a large amount of adenoid tissue, very soft and friable, in the vault of the pharynx. The larnyx was entirely normal. I advised that the adenoids be removed at once. This was done under cocaine on January 20 with little difficulty. He had a slight febrile movement and an excessively sore throat for several days thereafter, which cleared up.

Dr. H. T. Brooks, of the Post-Graduate Hospital, reported on January 13 that the patient's sputum contained "innumerable tubercle bacilli and quite a large number of streptococci." On January 29, 1904, Dr. Brooks made a second examination of the sputum and reported, "The examination required long-continued search to find tubercle bacilli, and when found they were present either isolated or in small groups."

The patient's general condition was much improved as the result of his operation, his nasal obstruction and the mucous hypersecretion being relieved at once. He was returned to Dr. Russell for further treatment, and I have not seen him since. I am informed, however, that Dr. Russell discharged him from further observation on May 8. He was then weighing 137 pounds, which was more than he had ever weighed in his life, and a gain of eleven pounds since February 1. Dr. Brooks on May 6 reported his sputum as negative.

Dr. Brooks' report on the adenoid describes it as showing structure of lymphadenoid tissue, practically normal except in six or eight small rounded areas of epithelioid cells separated by a fine fibrillated reticulum. One nodule showed a caseous center, at the margin of which was a large oval giant cell with chiefly polar nuclei. Several isolated giant cells were observed also within the epithelioid cell nodules, but always single and eccentric. These giant cells had fibrillated prolongations continuous with the inter-cellular reticulum above mentioned, "the collective features corresponding to the classical description of the histological structure of a tubercle nodule before caseation has occurred."

It is the writer's opinion that this was a case of primary tuberculosis of the hypertrophied pharyngeal tonsil. The history of two years' cough, growing worse eight months ago and accompanied by pains in the chest and sweating, together with the large quantity of bacilli found, would ordinarily indicate a fairly extensive lung lesion, which did not appear. Further, the cough which the patient had when he came to the writer was, to an experienced observer, much more characteristic of throat trouble than of lung trouble. Thirdly, the immediate improvement of the symptoms, together with the immediate and almost complete disappearance of bacilli from the sputum, certainly goes far to show that the tuberculous adenoid was the main lesion, if not the primary one. The writer wishes to express his obligation to Dr. Brooks for the painstaking care with which he made the difficult demonstration of tuberculous tissue in the adenoid growth.

56 East Fifty-third Street.

LE DIABÈTE À DEUX.

By LEONARD WEBER, M.D.,
NEW YORK.

It is rarely observed, and yet, among the three score of diabetic cases which have been under my care as the years have gone by, it has occurred three times, that the husband became rather acutely affected with diabetes after the wife had been a suf-

ferer from it for ten years or so. There was neither consanguinity nor similarity of constitution, disposition, or temperament in these cases; indeed, the two partners were mentally and physically about as different as could be; their domestic life, however, their habits, and the kind of food consumed had been the same for many years. They had always slept together in the old-fashioned double bed.

In diabetes, as in most other constitutional diseases, we are equally uncertain as to the how and why of its origin, and are still obliged to content ourselves with the "because" when we have established the fact that glycosuria is present. It may be permissible to think of the possible influence which the "acetone" exhaled with the breath, and the sweat of the diabetic might possibly have upon the health of the life partner who has been in close contact with the sufferer for years. The acetone inhaled for years, more or less, may through the blood and nervous system affect the physiological functions of liver and pancreas with regard to dextrose, so that glycosuria may develop. Further, there is the influence of the nervous system, which must be reckoned with in the etiology of family-diabetes, inasmuch as it is admitted that prolonged worry and grief may induce glycosuria. The hopeless state of health of a beloved person might affect her or his sympathetic friend in that way.

In the first case of double diabetes observed some twenty years since, the husband developed the usual chronic form about eight years after his wife had shown signs of it, and he died about five years after the wife's death; in the second, the husband followed with an acute case of the disease, which terminated fatally in less than two years. The third, under observation at the present time, again concerns the husband, the wife having diabetes for ten years or more, but the presence of sugar in his case, determined about ten months ago, is intermittent as yet and amounts to less than 1 per cent.

While it would be both cruel and unpardonable to mention the word "infection" to the patient in a given case, because no such a thing could be proved, the increasing number of cases of diabète à deux reported in medical literature would indicate that it is not desirable that a diabetic and non-diabetic person should habitually share the same bed.

85 West Forty-sixth Street.

The Influence of Breast Feeding on the Infant's Development.—Henry Dwight Chapin declares that the milk of the healthy mother is the best food for the infant up to the normal time of weaning. The milks of lower animals contain the same food elements as breast milk, but in different proportions. It has been shown that the composition of milks of different species of animals is closely related to the rapidity with which the young grow. A milk containing much proteid is intended for a rapidly growing animal. Many experiments have been made with a view to changing the proportions of the constituents of milk, but it has been decided that it is beyond the power of man to alter the character or composition of cow's milk, except by disturbing the cow's nervous equilibrium or digestion, or by underfeeding. Aside from extremes, the milk of any species has a fairly fixed type of composition satisfactory for the requirements of the young of that species. In artificial feeding the great difficulty lies in the inability of the infant to digest as much proteid as is found in mother's milk. Often the amount of proteid is reduced; but when it is remembered that the working parts of the body are built up from proteid, the advantage of the breast-fed baby over the bottle-fed can be easily seen, for the latter may be assimilating not more than half as much vital tissue-building food (proteid) as the former. Poor nutrition paves the way for illness. Mother's milk is not only food, as we consider food for adults, it is a food that adapts itself to the infant's developing digestive tract. The form that the mother's milk may assume after reaching the stomach depends upon the state of development of the stomach. At first the secretion of the stomach is the rennet ferment, which changes the casein into a soft curd, which is not digestible by pepsin. When the stomach secretes hydrochloric acid it combines with the curd and forms chloride of paracasein, which is readily digested by pepsin. Then gastric digestion begins. As fast as the acid and pepsin increase the mother's milk is able to use it up. As the child grows and the stomach increases in size and becomes stronger, it takes longer for it to empty, and the feeding intervals must be made longer. At birth the stomach secretes little digestive juice and digests little food, but mother's milk does not change in composition as lactation advances, unless at the time for weaning, when it may be poorer in solids. The milk is thus always ready to fit the developing digestive apparatus. The differences in milks are not so much nutritive as physiological ones. From a physiological standpoint, an artificially fed baby is a premature child. Cow's milk is physiologically adapted to a calf's stomach; human milk to the infant's stomach.—*The Journal of the Michigan State Medical Society.*

A Bacteriological Study of the Throat in One Hundred Cases of Scarlet Fever.—Jay F. Schamberg and Nathaniel Gildersleeve review the results of various investigators, adding their own list of 100 cases. The cultures were made between the second and sixth day of the disease. The blood of 20 patients was examined, with uniformly negative results. Cultures from the throat were made in the 100 cases, with the following results: Streptococci was found in 88 cases; staphylococci in 73 cases; a diplococcus corresponding to that of Class in 15 cases. This last microorganism sometimes appeared in short chains. The streptococci were, as a rule, of the ordinary type. The virulence of the staphylococcus cultures varied to some extent. The writers declare that until the streptococcus found in scarlet fever is shown to possess properties which trenchantly distinguish it from other streptococci, and until this disease is experimentally produced by inoculation of a pure culture of such an organism, the belief in the casual relationship of the streptococcus to scarlet fever cannot be maintained. They conclude that streptococci and staphylococci are to be found in the throat in the vast majority of cases of scarlet fever, but the former are present in a very large percentage of apparently healthy throats. Both organisms are frequently concerned in the complications of scarlet fever, but they do not look upon either one as the specific agent. The diplococcus described by Class as the cause of the disease was found by them in but a comparatively small percentage of cases, and they do not regard this organism as bearing any etiological relationship to the disease. The finding by Mallory of protozoa-like bodies in the skin of scarlet fever patients will, the writers think, stimulate research, and they suggest that the failure in the past to discover the contagium vivum of the disease has been due to the fact that almost exclusive search for vegetable parasites has been made.—*Medicine.*

The Invention of Spectacles.—Father Delatre has communicated to the French Medical Society of Tunis the discovery in a tomb near the ruins of Carthage, and dating from at least the second century B. C., of a pair of glass lenses, flat on one side and slightly convex on the other. The convexity is too slight to make them of any use as magnifiers, but would serve admirably to correct a slight presbyopia. The unfortunate absence of anything in the shape of a mount or frame is the only reason for doubting that they were used as spectacles, which would make the invention of those instruments fifteen centuries earlier than is generally supposed.—*Gazette Médicale de Paris.*

MEDICAL RECORD.

SUCCESSFUL TREATMENTS OF INOPERABLE CANCER.

LAST year we had occasion to notice the remarkable results reported by Adamkiewicz, of Vienna, from use of his cancroin in cases of inoperable cancer, results which have since received confirmation at the hands of at least one other observer. It may be interesting to note briefly the following three cases treated with equally good results as regards recession of the growth and the removal of symptoms by three different methods, no one of which bears any obvious relation to that of Adamkiewicz. The first of this series is a case of cancer treated by the Roentgen rays; the second and third are cases of epithelioma, treated by hypodermic injections of soap and of Chian turpentine, respectively.

The first case is reported by Prof. E. Schiff, of Vienna, in the *Bulletin of the Johns Hopkins Hospital* for June last. After reviewing former attempts in this direction, he insists on this case on account of the favorable result and because he was able to study it histologically. The case is that of a married woman with the left thorax invaded by a very solid tumor with large base, extending from the sternal margin to the axilla, where it reached the glands. The surface was ulcerated with fetid discharge and bleeding slightly when touched. The back also showed five small nodules. In the axilla was a crateriform cavity the size of a pigeon-egg, with gangrenous edges and necrotic base, full of purulent matter. The supra- and infraclavicular glands were hard. After the third sitting of *x*-ray applications the pains decreased considerably, as also the purulent secretion. Almost daily an improvement could be noted. After four months' treatment a flat scar crossed by some enlarged capillary vessels and with some slight superficial excoriations had replaced the tumor. The cutaneous metastases had disappeared and the hard supra- and infraclavicular glands had become soft. The general condition was greatly improved. Histological examination showed the growth to be cancerous.

The second and third cases are reported by Col. T. Ligertwood and Mr. John A. Shaw-Mackenzie in the *Journal of the Royal Army Medical Corps.* The second case was one of cancer of the tongue of six months' duration in an old soldier of seventy-eight years. Under hypodermic injection of 5 minims of a 1 per cent. soap solution (as recommended by Webb on the theory of local injury or of defect of soap in the biliary secretion permitting the separation of cholesterine from the living cell), and increased by 5 minims every other day until the full dose of 60 minims was reached, marked cessation of all pain and of fetor ensued, with ability to open the mouth, protrude the tongue, and take minced meat, while the growth diminished from the size of a walnut to that of a half filbert. Indeed, toward the end of treatment no appreciable thickening existed. Throughout the treatment the patient also suffered from advanced cardiac and arterial degeneration, and finally developed œdema of the extremities, which passed into black gangrene of the left leg and foot, with rapid sinking and death. Post mortem the appearance of the tongue differed very little from normal, but microscopical examination of sections through a small patch of ulceration and through a gland under the ramus of the jaw demonstrated epithelioma.

The third case was one of epithelioma of the neck in an old soldier aged seventy-three years. There was a large, hard, fixed mass, ulcerating in places, over the middle of the right sternomastoid muscle, extending up toward the mastoid process, under the ramus of the jaw, and in front over the trachea. The head was tilted to the left, great pain was present, and swallowing was becoming difficult. The growth began as a pimple some months before, and was evidently increasing. Microscopical examination showed it to be epithelioma. January 25, 1904, 5 minims of a 20 per cent. solution of Chian turpentine in sterilized olive oil was injected subcutaneously, the dose being increased by 5 minims every other day until one of 20 minims was reached. The third injection (of 15 minims) was followed by a temperature of 102°, returning to normal the next morning, and the 20 minim dose produced a rise to 103.6°, necessitating a reduction to 5 and 10 minim doses, which caused a rise to about 100°. Almost from the first injection all pain ceased, the extensive redness of the surrounding skin, reaching from above the mastoid on to the chest, subsided rapidly, leaving a faint purple discoloration in the immediate neighborhood of the growth; the ulceration decreased and the discharge became purulent and free from odor. The head was no longer tilted and could be moved freely, the dysphagia disappeared, and at the end of a month the mass had diminished astonishingly in all directions. At the time of writing (May 30) the mass was about the size of a hen's egg, and was shrinking slightly from week to week. There was a purulent, but inoffensive, discharge from the ulcerated surface.

The practical moral would seem to be that cases so hopeless in their natural evolution should not be abandoned without a rational experimentation along some one of these lines.

CARBOLIC ACID TREATMENT OF INFECTED WOUNDS.

SO MARKED has been the trend of surgery towards asepsis and away from antisepsis in the old sense of the word,—in the sense which brings back memories redolent of iodoform and carbolic acid—that a prominent Russian surgeon, G. I. Turner, of St. Petersburg, has found necessary recently to write a fervid defense of the antiseptic treatment of infected wounds (*Russki Vratch*, June 26, 1904).

Turner believes that the adoption of the two seem-

ingly antonymous terms, asepsis and antisepsis, was a misfortune for surgery. As a matter of fact, the Russian author says, the terms asepsis and antisepsis are essentially identical in meaning. Of the two, he thinks that the latter is more accurate and more appropriate. As Lockwood has well said, antisepsis is a method whereby asepsis may be secured. There is no difference in what manner asepsis is produced, provided the body does not suffer thereby. Whether we sterilize the instruments or disinfect a wound, we are taking antiseptic precautions, just as in rendering choleraic stools harmless we are adopting "anticholeraic" measures, which no one would think of calling "acholeraic."

With this as a text, Turner goes on to describe the advantages of the method of antiseptic treatment of infected wounds advocated by the American surgeon, Phelps, viz., the use of pure carbolic acid, followed almost immediately by pure alcohol. The use of pure carbolic acid was first suggested by Godson (*British Medical Journal*, November 26, 1898) in compound fractures, ulcers, etc. In 1901, Fraser recommended it as an application to the affected area of skin in erysipelas (*British Medical Journal*, May 1, 1901). Phelps' article appeared in German in the *Münchener Medicinische Wochenschrift*, No. 38, 1900, and this surgeon reports having used carbolic acid in over seventy cases of tuberculous abscesses in connection with hip disease. He believed that he had saved twenty of these cases from resection of the hip joint by this method. His treatment was as follows: On opening the joint-cavity or the abscess, as the case may be, the interior is widely exposed, and if the end of the bone be diseased it is scraped with a sharp spoon, the joint is irrigated with a one to two-thousand solution of mercuric chloride, and is then filled with pure carbolic acid. The latter is allowed to remain exactly one minute, after which it is washed out thoroughly with pure alcohol. Finally the alcohol is removed completely with a two per cent. solution of carbolic acid. The wound is not sutured, but is dressed with a drainage tube of glass containing gauze which is passed to the bottom of the joint cavity. The object of this is to enable the surgeon to watch the progress of healing and to scrape again if need be, or to renew the treatment.

A number of surgeons since Phelps have reported good results with this method, notably Hansell, who was assistant to Bruns, and who related his experiences at the Surgical Congress held in Berlin in 1901 (*Centralblatt für Chirurgie*, Beilage zu No. 29, 1901). Turner himself reports a number of cases of simple abscesses, suppurating atheromas, tuberculous joints, etc., in which he used the Phelps treatment with marked success, employing, however, a sixty per cent. solution in pure alcohol instead of the pure acid. He was astonished at the aseptic and "reaction-free" manner in which the wounds healed, and in view of these results cannot see how any one can be fanatic enough to preach against the "antiseptic method."

Happily for us in America, we have passed long since through the period when asepsis was preached as against antisepsis. Clinical experience has shown that both are needed in their places, and so there cannot be any objections to Phelps' method on these grounds. Judging from the results obtained by Turner and his predecessors, the method is worth employing in selected cases of wound infection. The successive use of carbolic acid and alcohol over limited surfaces of infection is, indeed, one of the favorite methods in the hands of many surgeons to-day.

The Personnel of the Navy.

Medical Inspector Howard E. Ames, U. S. N., has written recently a paper, published in the "Proceedings of the United States Naval Institute," Vol. XXX, No. 1, entitled "A Plea for a Higher Physical, Moral, and Intellectual Standard of the Personnel for the Navy." According to the writer, there is a lack of a proper standard for the admission of cadets to the academy at Annapolis. "Physical soundness," as specified in the circulars sent out by the department, is a vague condition in some respects, and leaves open many questions that are of the greatest importance, such as weight for age, weight for height, height for age, chest measure for age. Dr. Ames thinks that the whole subject of physical requirements should be thoughtfully considered by a board carefully selected from the medical and line officers of the navy. This board should study the matter in all its bearings, and from its report a standard might be fixed which, after careful consideration by higher authority, would be adopted and made binding by legislative enactment. It would seem from a perusal of Dr. Ames's paper that the conditions ruling at Annapolis with regard to the physical qualifications of cadets are not nearly severe enough, and that reforms should be instituted whereby the officers of the United States Navy should be warranted as sound in wind and limb and in every respect fine physical specimens of the American "genus homo."

The writer has also much to say concerning the efficiency of the enlisted force. He is of the opinion that, as a rule, the officers composing the recruiting party are not suited for the work and do not realize the importance of the duty, quantity instead of quality seeming to be the incentive. In consequence of this carelessness, the men enlisted frequently present grave physical defects, and are in no way fitted to undergo the arduous duties which fall to the lot of a man-of-war's-man. As to the morals of the enlisted men of the navy, Dr. Ames states that many degenerates succeed in passing the medical examiner and get into the service, but, although this often happens, he can find no reason for their retention after they are discovered. It goes without saying that the moral condition of the personnel is a matter of supreme importance, and has a very strong bearing upon physical soundness.

The Lust for Operation.

This is the title of a paper which was read by Dr. Hatherley, of Wangamie, at the annual meeting of the New Zealand branch of the British Medical Association and published in the *New Zealand Medical Journal*, April 30, 1904. As may be gathered from the title, Dr. Hatherley is no believer in surgical operations except when they are absolutely necessary, and strongly holds the view that surgeons often use the knife when the circumstances of the case do not call for such a procedure. In fact, the writer feels confident that operations are frequently performed for the mere "love of the thing," and he also opines that this practice is on the increase. The "lust"—which word he uses advisedly—for operation becomes an obsession, which so holds those possessed of it in its grip that they will go to almost any lengths to satisfy their craving.

Dr. Hatherley instances the operation for appendicitis as a conspicuous example of this "lust for operation." He points out that the leading English textbooks on surgery state almost unanimously that a large proportion of cases go on to recovery without surgical interference, sometimes even when there is evidence of grave local mischief. This statement agrees with the results of his experience. The operation for the relief of floating kidney and the removal of the tonsils and of adenoid growths are also condemned by Dr. Hatherley as in a large proportion of cases unnecessary.

The speaker implied that there was a commercial as well as a professional aspect of the operating craze, as in a great many diseases it is infinitely more remunerative to operate than not to operate. He likewise took a tilt at the size of the fees charged for present day operations, especially for such comparatively simple operations as those for removing tonsils and postnasal growths. Dr. Hatherley concludes by advancing the argument that a good surgeon is not always an expert operator, and, conversely, a brilliant operator is not necessarily a sound surgeon, and thinks that the preservation of a limb demands a higher order of skill than the amputation thereof.

Not a few voices in other parts of the world than New Zealand have been raised in protest against the increasing resort to operative measures, and it has been often questioned whether the resource to the knife has not been carried to excess. At any rate, the fact is too evident to admit of any denial that this is the age of the operating surgeon. Perhaps ere long the wheel will turn and we shall revert to a more conservative treatment.

The British Public House Trust.

One of the features of the present crusade against drink in Great Britain is the public house trust which has recently been established there. There are now in England, Scotland and Wales 150 saloons controlled by this trust. The enterprise originated in 1877, when a clergyman in Warwickshire, who had become trustee of a village inn, conducted it on the "Gothenburg" system—the main principles adopted being that the liquor should be of good quality and that the manager should have no interest in increasing its sale.

In 1901 Earl Grey formed the Central Public House Trust Association, for the purpose of establishing a branch in every county, and at the present time local trusts have been established in all but five of the counties of England. Trusts have also been formed in Ulster and South Wales. In Scotland the movement has met with much success. The effect of the saloon as an enemy to the public health does not lie in the fact alone of the direct injury done by drink. Saloons, and especially those in the lower districts of a city, are centers whence disease germs are likely to be spread. Many of them are unsanitary, ill-ventilated, and in every respect provide conditions in which disease may easily be disseminated. The movement for the establishment of saloons properly controlled and managed is one in the right direction and in the interests of health and morality.

Consumptives in Factories.—At the factories of Messrs. J. S. Fry & Sons, Bristol, England, there are 2,000 girls and women under 54 superintendents. All persons found to be tuberculous are suspended from work, put on the sick fund, and sent to a sanatorium as soon as possible. These are not allowed to return, bt are assisted to find work elsewhere, or are pensioned.—*Public Health.*

News of the Week.

Mourning for Finsen.—The funeral of Prof. Niels Finsen, who died on September 24, was held in the Frederick Church, Copenhagen, on September 29. Few scientists have received such posthumous honors as he. According to the despatches, two kings, those of Denmark and Greece, were present, and almost every other European ruler was personally represented, while princes, ministers of state, and leading scientists came to pay a last tribute to the dead man. Wreaths carried by special representatives came from Emperor William, King Edward, Queen Alexandra, and Count von Bülow, the German Imperial Chancellor. The Crown Prince of Denmark and Princes Waldemar, Karl, and Hans were present in the church.

Beriberi in the Japanese Army.—One of the most serious problems confronting the Japanese army surgeons at the seat of war is the prevalence of Beriberi. It is stated that the losses from this disease exceed the total casualties in the fighting. Every transport bound for Japan takes hundreds of sufferers. One General has been invalided by the disease. The besiegers of Port Arthur are suffering the worst, and it is said that between this disease and casualties one division has been almost extinguished. The cause of the outbreak is unknown, though believers in the nitrogen-starvation theory of the disease find support for their views in the epidemic.

Impersonating Candidates at the Regents' Examination.—Two young men were recently arrested for impersonating candidates for certain offices at a Regents' examination, and it is alleged that such practices are not uncommon. A prosecution for a similar offense occurred two years ago, when a physician was caught acting as proxy for a candidate for a medical license. Both pleaded guilty after being indicted, but sentence was suspended. In that case the physician lost his own license and the other man lost all chance of ever getting one.

Suit to Recover a Large Fee.—A wealthy American has begun suit in Paris against a surgeon of that city to recover 100,000 francs, which sum he alleges was extorted from him by the surgeon, who was treating the complainant's wife. The plaintiff states that his wife was suffering from a cancer which had been declared inoperable by a number of competent surgeons in this country and Europe, and that she was induced to submit to treatment by injections of a serum prepared by the Paris surgeon, by the use of which she was persuaded to hope a cure might be effected. The treatment was begun, but without any agreement regarding the fee, although the plaintiff alleges that he asked for a statement of the surgeon's terms repeatedly. Finally, two weeks after the injections were begun, the "business agent" of the surgeon presented a bill for $100,000 francs ($20,000), and urged immediate payment on the ground that it was customary in France to pay in advance for surgical treatment. The plaintiff, fearing the effect upon his wife of a suspension of the treatment, was constrained by what he terms in his complaint "moral violence" to pay the fee demanded. The treatment did not stay the progress of the disease, and the patient died within a couple of months after beginning the injections. Mr. Crocker, the plaintiff, announces his intention, in case the surgeon is compelled to return the sum paid, or any part of it, to give the money to the Pasteur Institute. According to Paris correspondents of the daily press, it is a not unusual practice of certain surgeons of that city to make excessive charges in the case of a rich American who may fall into their hands,

and to secure payment by this sort of "moral violence." Another incident, and similar to the one above related, which has not yet reached the courts, occurred recently. A prominent citizen of Pittsburg entered the hospital of a leading specialist in order to be operated on. When the treatment had reached a critical stage the American was required to pay $4,000, which was done under protest. It is only fair to say, however, that such sharks are few in number, and that the reputable French practitioners, of course, condemn the practice. One of the foremost of these recently performed a major operation on a little Brooklyn girl, remaining by her bedside continuously for thirty-six hours. Thereafter, learning that the family had only moderate means, the physician declined to accept any remuneration.

More Trouble for the Sydenham Hospital.—A young woman who was a nurse in the Sydenham Hospital, in this city, has brought suit against the board of directors of the hospital for $2,000 damages for loss of time. She says she went there in August last year on the promise of a diploma when her course was finished, and didn't get one. Charges against the hospital were recently made by some physicians, formerly members of the attending staff, but were dismissed by the State Board of Charities, which decided it had no jurisdiction in the case.

Excitement in Bellevue Hospital.—The rooms occupied by members of the Bellevue house staff were formerly cared for by men, who not only made the beds and dusted, but acted as valets for the doctors. For some reason the hospital authorities have dismissed the men and taken on elderly maids in their places, and the young men now have to brush their own clothes, and are displeased by the change.

Illinois State Board of Health Circular on Consumption.—The State Board of Health, through its secretary, Dr. James A. Egan, recently issued a third revised edition of its circular on the "Cause and Prevention of Consumption." Illinois is commended as a proper place for the treatment of consumptives, and considerable attention is drawn to climatic conditions, elevation and soil, which is referred to as being equally as good as, and in some instances superior to, those found at the well-known sanatoria for the tuberculous of Massachusetts, New York, and Pennsylvania. It is said that $10,000 has been offered to the State Board for the purpose of constructing a consumptive hospital. Much information is given in the sections of the pamphlet on the care of the consumptive, prevention of consumption, and consumption in schools.

Food Inspection by the Board of Health.—The Department of Health of New York is preparing to make a more rigid inspection of food products sold in the city. Two extra chemists have been added to investigate the extent of adulteration, and the department this year will spend more money along this line than heretofore. The new chemists are now engaged in examining syrups for adulterants or deleterious combinations.

Opening Exercises of the Chicago Colleges.—On September 27 the opening exercises of the College of Physicians and Surgeons were held in the large amphitheatre. The principal address was delivered by Dr. C. C. O'Byrne. The opening exercises of the American College of Medicine and Surgery were also recently held, at which time addresses were made by Dr. Truman W. Brophy and Prof. Gammage. Fifty-one freshmen matriculated.

Illinois Medical College.—The commencement exercises of this college were held September 29 at Handel Hall, Chicago. Degrees were conferred upon 47 doctors and druggists by Dr. H. H. Brown. The principal address was delivered by Judge Holdom. A banquet was held in the evening at the Auditorium Hotel. Dr. S. S. Bishop acted as Toastmaster, and speeches were made by several members of the Faculty.

Typhoid Fever in New York State.—The State Board of Health is receiving reports which show the usual autumn increase in cases of typhoid fever in all sections of the State. This is easily traced in most instances to the contamination of country wells, the sufferers being in great part those who have passed their summer holiday on some farm where the well receives the seepage from neighboring privy vault.

New York and New England Association of Railway Surgeons.—The fourteenth annual meeting of the New York and New England Association of Railway Surgeons will be held at the Academy of Medicine, New York City, November 17 and 18, 1904, under the presidency of Dr. C. G. J. Finn, of Hempstead, Long Island. Railway officials and all surgeons interested in this work are cordially invited to attend. The secretary of the association is Dr. Geo. Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

Illegal Practitioners in California.—The State Board of Medical Examiners of California has announced that it will no longer take the initiative in the prosecution of those who practice medicine in violation of law, and it calls upon the county medical societies to assume that duty.

Dr. A. E. Macdonald retired from the superintendency of the Manhattan State Hospital East, Ward's Island, New York, on October 1. Dr. J. T. W. Rowe is at present acting superintendent of the hospital.

Effective Treatment.—A San Francisco physician recently certified to the Board of Fire Commissioners that one of the firemen "will be unable to perform any physical duty while he is taking my treatment." The Commissioners cruelly suggested that it would be well to discontinue the treatment at once.

The Pacific Association of Railway Surgeons held its first annual meeting in San Francisco on August 17 and 18, followed, *secundum artem*, with a banquet.

The Health Department of the City of Los Angeles should be commended for its persistent efforts to increase the salary of its bacteriologist to $1,800 a year, and none the less because the incumbent is a woman.

Dr. A. V. Phelps, of Cincinnati, has been appointed secretary of the Medical College of Ohio to fill the vacancy created by the death of Dr. James G. Hyndman. Dr. Phelps is a graduate of the Medical College of Ohio and has served as professor of histology and in recent years as professor and demonstrator of anatomy. Just after leaving college he served as interne and house surgeon to the Cincinnati Hospital.

Dr. George F. Butler, formerly of Alma, Michigan, has been appointed professor of therapeutics in the College of Physicians and Surgeons, and professor of medicine in the Dearborn Medical College, Chicago; he has also been appointed attending physician to the Samaritan Hospital.

The Cincinnati Academy of Medicine held its opening meeting on September 26. A committee was

appointed composed of Drs. Conner Reamy, Nichols, and Palmer to draft resolutions on the death of Dr. James G. Hyndman.

The Late Dr. Victor Steinberger.—The following resolutions have been adopted by the associates of the late Dr. Steinberger in the Board of Health.

Whereas, We feel that in the untimely demise of our esteemed co-worker, Dr. Victor Steinberger, we have lost a genial companion, an arduous worker, a progressive physician and an earnest and sincere colleague,

Therefore, Be it resolved that we medical inspectors and trained nurses of the Department of Health of the City of New York, Borough of Manhattan, at a special meeting held on July the twenty-third, nineteen hundred and four, extend to his widow and to his family our heartfelt sympathy in the hour of their bereavement.

May the remembrance of his affable personality, his conscientiousness in his duties, his devotion to his beloved ones, and his uprightness of character, serve to lighten their grief, to strengthen them in their affliction and be a blessed memory in the future.

And be it furthermore resolved, that these resolutions, suitably engrossed, be presented to his widow, and that a copy be published in the city medical journals.

Committee: Jacob Sobel, M.D.; Edward M. Thompson, M.D.; E. Helen Knight, M.D.; Otto A. Jahn, M.D.; L. Marcus, M.D.; Henry J. Blumensohn, M.D.; Thomas W. Neapsey, M.D.

Obituary Notes.—Dr. David D. Wickham died at his home in Port Jervis, N. Y., on October 1, of acute gastritis, at the age of seventy-four years. He was born in Wantage, Sussex county, and received his degree from the Syracuse University College of Medicine with the class of 1875.

Dr. John Purcell, a retired practitioner of this city, died at Larchmont, N. Y., on September 26, at the age of eighty-six years.

Dr. Phineas Jonathan Horwitz, of Philadelphia, formerly medical director of the United States Navy, died at Bar Harbor, Me., on September 28. Graduating from the medical department of the University of Maryland in 1845, he was two years later appointed assistant surgeon in the United States Navy. During the Mexican War he was in charge of the hospital at Tampico.

Dr. Silas Updegrove died at Philadelphia on October 1 at the age of seventy-five years. He was graduated from the Medical Department of the University of Pennsylvania in the Class of 1854. He served as a surgeon in the United States Army during the Civil War and he was at one time coroner's physician.

Dr. Isaac MacBride died at Philadelphia on October 2 at the age of seventy-three years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1854.

Dr. Merric Bemis died at his home in Worcester, Mass., on October 3, at the age of eighty-four years. He was a graduate of Castleton Medical College, Vermont, in the class of 1852. From 1857 to 1872 he was superintendent of the Worcester Insane Asylum, and was widely known as an expert on insanity. He was a member of many national, state, and local medical societies.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent)

SANITARY INSPECTORS—SIR THOS. BROWNE—A PENNY HOSPITAL FUND—HISTORY OF ST. BARTHOLOMEW'S—NEW DIRECTOR OF NAVAL MEDICAL SERVICE—OBITUARY.

London, September 16, 1904.

Sir James Crichton-Browne opened his address to the sanitary inspectors at Bournemouth by reference to the clean bill of health of the town, which he pronounced a shrine at which they might well come to worship. Then he went on to say that the days were nearly passed when the Bœotian intelligence thought that a tinker or tailor could smell out nuisances or a baker or barber be a good judge of meat. The inspectors were now well informed and upright, drawn from a superior class, and well fitted for their onerous duties. He hoped the time was not far off when a certificate of efficiency from some examining body would be required of all inspectors, and suggested that the University of London might grant such certificates after a liberal curriculum. Thus he would saddle us with another diploma. The faith in examinations seems spreading in all directions, and I suppose we shall go on multiplying diplomas until the distinction will be to have none. Sir James then referred in some detail to plague epidemics and confirmed, in contravention of Lord Curzon's recent remarks, that administrative energy in sanitation has greatly restricted its ravages and promises to control them in future; it is still a grizzly terror to mankind, but in this country, strong in our sanitary equipment, we may regard it with equanimity. All sanitary work has widespread effects, but has to undergo special adaptation. In the case of plague the peculiarity is rats, and without waiting for an epidemic a crusade against them should be undertaken. They are useless, altogether noisome, and probably promoters of other diseases besides plague. They should be exterminated, and he would enlist the sporting propensity to assist in the process. Rat-catching was as exciting and quite as elevating as pigeon shooting. The sporting papers should describe the battues, report the bags, and give portraits of the record-breakers, for great things might be expected when sport, fashion, and sanitation joined hands. In conclusion, Sir James said that never before had the public mind been so stirred by sanitary hopes and fears. The scales are falling from men's eyes. They are beginning to see that the future of the race and the happiness of the individual hinges on the microbe, so long skulking in the dark, but now dragged into the light. But the great battle of sanitation has yet to be fought, the skirmishes have taken place, and in the coming battle inspectors will be in the thick of it, but they will be supported by the engines of science and the good will of the people.

Dr. Conolly Norman protests with almost unmeasured anger against the proposal to erect a memorial to Sir Thomas Browne. He declares the author of *Religio Medici* to be a favorite author of his, but says medical men should be the last to subscribe to a memorial on account of his views on witchcraft. He instances the trial of the two witches condemned at Bury in 1664, when Sir Thomas gave evidence which makes Dr. Norman speak of his record as "stained with innocent blood" and other crimes, with a suggestion that his evidence must be read charitably "if we are not to add perjury to his other faults." So angry is Dr. Norman, who takes the story from Rev. Dr. Hutchinson's *Essay on Witchcraft*, that he talks of the "cowardice and muddle-headedness" of the judge, who was no other than Chief Baron Hale, generally held to be the most able judge who held that office and who afterwards became Lord Chief Justice. Of course replies are forthcoming, in which it is urged that Browne's views must be judged by the common beliefs of the 17th, not the 20th, century; that his reputation rests on his literary ability, not on his scientific foresight, or even his medical acquirements, and that few of us would care to be judged by the standards that may be set up two or three centuries hence.

We are threatened with another hospital fund. The editor of a weekly paper proposes "a penny fund." He estimates there are 30,000,000 people in Great Britain who never give a penny to hospitals, and say if each would contribute that small coin more than £130,000 would be realized. But how are these millions to be reached? I leave the problem to the editor, and I do not think he will be fortunate enough to solve it. Perhaps we have organizations enough already, and the penny fund is not destined to do much.

A different line is taken by the appeal committee for St. Bartholomew's Hospital. They are soliciting subscriptions

for a "complete history" of their charity, 1123-1905, which has been written by Dr. Norman Moore, and is to be sold for the benefit of the rebuilding fund. The work is illustrated by Mr. Howard Penton, and the price, one guinea, in cloth, or two guineas, in extra binding. Many Bart's men will doubtless be glad to have a full history of their venerable *alma mater*.

Inspector-General H. M. Ellis has been appointed Director-General of the Medical Department of the Navy, *vice* Sir H. F. Norbury, K.C.B., whose term of office has expired.

Surgeon-General Jameson, C.B., late Director-General of the Army Medical Service, died on Tuesday, aged 67. He entered the service in 1857 and went to Canada to join the 47th Regiment which he accompanied to the West Indies, where he was promoted for "his highly meritorious services during an epidemic of yellow fever." He had charge of an ambulance in the Franco-German War, and was employed at the siege of Paris and on the campaign on the Loire. By special grace the Emperor William I. conferred on him the commemoration medal. He rose through the various ranks up to surgeon-general. In May, 1896, he was made director-general, and retired with honors in June, 1901. He had the Canadian medal and clasp, was made C.B. in 1897, and also Honorary Surgeon to Queen Victoria and afterwards to King Edward. He was also given a good service pension and was a Knight of St. John of Jerusalem.

The death has also occurred of Inspector-General D. MacEwan, M.D., aged 78. He entered the navy in 1847 and served in China, India, Burma, the Russian war, and South America. He received a number of decorations, including the medals for Burma and the Baltic. For seventeen years he was in attendance on Queen Victoria when on the royal yacht. He was Honorary Physician to Her Majesty, and since then to King Edward.

Fleet Surgeon Joseph Wood, R.N. (retired), dined on the 5th inst., aged 62.

Surgeon-Major John Campbell, C.B., M.D. (retired), died on the 2d inst., aged 87. He served in the Afghan War, 1841; in Scinde, 1843, and in the Mutiny, 1857, and was decorated for his services at Lucknow.

Dr. Wm. Lee Dickinson died suddenly on the 6th inst., aged 40. He graduated at Cambridge, M.B., 1890; M.D., 1893, and was elected F.R.C.P., 1894, the earliest date possible, as he was a member of 1889. He was physician to St. George's Hospital, where his father, Dr. Howship Dickinson, was so long physician and passed on to the consultant staff on his retirement. Dr. Lee Dickinson contributed to the Royal Society's "Proceedings," the *Journal of Physiology*, Allbutt's "System of Medicine," and American and British medical periodicals.

Dr. Dudgeon died on the 8th inst, in his 85th year. He graduated at Edinburgh in 1841. He soon after took up homœpathy and edited a journal devoted to that school for about 40 years. He will be better remembered by his work on the sphygmograph.

OUR BERLIN LETTER.

(From Our pecial Correspon lent.)

CELEBRATION OF KOCH'S BIRTHDAY—NEW HYGIENIC INSTITUTE —THE RUDOLPH-VIRCHOW HOSPITAL—DEATH OF KÖBNER AND LANDERER.

BERLIN, September 14, 1904.

THE following is the report, somewhat delayed, of a celebration, worthy of notice by the public. In the last semester, a number of the most distinguished physicians united to celebrate the sixtieth birthday of Robert Koch. But as at that time Koch was far from Berlin the formal celebration took place after his return, August 23. After addresses by Waldeyer, Kirschner, and Gaffky, Koch's bust was presented to him, and his remarkable answer is worthy of being placed on record. "It is an unusual honor," he said, "for you to celebrate my sixtieth birthday, as it is only customary so to recognize the seventieth. I confess that I was much surprised when I first heard of your project. On the other hand, I am glad you have chosen this time, and for the reason that, as you know, all is not honey for the investigators in our specialty. The good old times when one could count all the bacteriologists on his fingers, and could explore, undisturbed, a great part of our scientific realm, have long since passed. Now there is but little free field, and there are unnumbered competitors in its cultivation, each wanting his share. Even among the most modest and considerate workers one frequently jostles his neighbor or treads on his toes, so that, even before it could have been expected, one is surrounded on all sides by adversaries. That is disagreeable and takes much of the peace and joy from the work. I have my own grievances to complain of in this line. Regardless of what I say or write, I meet with violent opposition, and that from those who understand little or nothing of the matter, and, therefore, are not fit to judge. Already the idea of giving up the game has often come to me. But when I see by this day's celebration that I have so many friends who take part in my work, and on whose understanding and assistance I can rely in case of need, all ill humor and hard feeling pass from me. I shall indeed give up the constantly increasing burden of the administration of my institution for infectious diseases. But this step does not mean that I shall become faithless to our science. On the contrary, I now promise to work with and for you as long as I have the ability."

The place of Koch's former activity, the Hygienic Institute, in Kloster street, which he established in 1895, is now to be entirely abandoned. The buildings, even then very old and furnished by Koch with a very simple equipment, are now considered useless. Rubner, Koch's successor, is, during the next semester, to remove to the new Institution in Hessian street, near the other medical buildings.

I may use the vacation time of the surgical societies to give a brief survey of the Rudolph-Virchow Hospital, the new Berlin hospital, with accommodation for two thousand patients. Although it will not be opened till the spring of 1906, it should claim the attention of our American colleagues who visit Berlin, for it is to be our largest and most beautiful hospital, and the one with the most modern equipment. Already one can see that this hospital will seem restful and pleasant to the patients, a fact in itself of great help to the physician. It is to be surrounded with a wall of wrought iron, with here and there openings giving a view of the street and its life. In front and in the center are the large and imposing administration buildings, with a wing extending to the street. At the sides are buildings with light walls and red roofs, to be used as officers' houses, and also for the lying-in hospital, and for genito-urinary diseases.

A beautiful view greets the visitor as he passes out of the main building by its middle door. A long road lies before him, bordered by lawns and flower beds, and shaded by two avenues of chestnut trees. On the left are the buildings belonging to the surgical department, and on the right those belonging to the medical department. These buildings look like country houses surrounded by lawns and hedges. The walls are covered with green vines, and there are to be flowers in the windows. At the rear is situated the anatomical building, and in connection with this, but not visible from the patients' quarters, is the morgue, with a door opening on the street. To the left of the central building, and entirely isolated, is the department of infectious diseases; on the right, the building for lighting, washing, and cooking, and the great water tower with its reservoir. These last-named buildings face an open street leading directly to the main front, and are invisible from the patients' side. These buildings are the best work of the architect, L. Hoffman. The former factory-building style has given place to a beautiful form of architecture, which will become classical for similar structures. But it is necessary to see this magnificent work to appreciate it.

The Berlin medical world has lost two excellent pioneers, Heinrich Köbner and Albert Landerer. In the history of medical universities Köbner's name will never be forgotten, inasmuch as he was the first to hold a professorial chair of dermatology in Germany. His studies in this specialty were carried on in Paris and Vienna, and afterwards in Breslau he founded the first clinic for skin diseases. In 1869 he qualified as university lecturer, and was made professor in 1872, in spite of the opposition of the medical faculty. In 1876 he was appointed director of the newly established clinic for skin diseases. Leaving Breslau because of ill health, he became later distinguished in Berlin as a skin specialist. His studies in sycosis, syphilis, leprosy, psoriasis, carcinomatosis, and pemphigus have lasting value.

Albert Landerer was professor of surgery in Leipsic, and, since 1884, chief of the surgical department in the Karl Olga Hospital in Stuttgart. In 1902 he moved to Berlin, having been elected surgeon-in-chief of the new hospital, Berlin-Schömberg, yet in course of construction. He died on a pleasure trip in Switzerland, and could not see his plans perfected. He was the author of many monographs in general and special surgery, and also of several manuals. He was known chiefly by his use of cinnamic acid in the therapy of tuberculosis. Although his method has recently been extensively tried, no final judgment as to its value can yet be given.

OUR CANADA LETTER.

(From Our Special Correspondent.)

MEDICAL PROTECTIVE ASSOCIATION—VITAL STATISTICS OF MONTREAL—SENATE ELECTION TORONTO UNIVERSITY—DR. WILLIAM OSLER'S APPOINTMENT—ONTARIO LIBRARY ASSOCIATION—CRUSADE AGAINST QUACKERY—ONTARIO HEALTH REPORT—DOMINION REGISTRATION.

September 25, 1904.

The Canadian Medical Protective Association held its annual meeting in Vancouver recently. Dr. R. W. Powell, of Ottawa, was elected president, and Dr. James A. Grant, Jr., of Ottawa, secretary and treasurer. The association is doing good work, and affords medical men a protection that is now more appreciated than ever. The annual fee of $2.50 is not by any means excessive, but it is found sufficient. Since its organization the association has done excellent defense work and has defended several cases against its members to a successful termination. It is managed without expense, being conducted entirely by medical men, who give their time gratuitously on behalf of the profession.

The last report of the vital statistician for Montreal shows in that city an increase in the birth, marriage, and death rates. The death rate increased from 22.58 per 1,000 in 1902 to 24.29. The birth rate increased from 35.65 to 36.08 per 1,000, while the marriage rate increased from 9.22 to 10.16 per 1,000. The increase in the two latter rates may be due to the fact that sermons were preached in the Roman Catholic and other churches about two years ago against the falling off in the birth rates.

Considerable interest is manifested just now in the pending election of medical representatives to the Senate of Toronto University. The success of the union of Trinity with Toronto University will probably be seen in the result of the election. Each medical graduate can vote for four representatives on the senate. The ballots have been distributed and are returnable before October 10.

The medical men of Canada are much rejoiced in the honor which has come to a Canadian physician, who is well known in every part of this country, in the appointment of Prof. William Osler, of Johns Hopkins University, Baltimore, as Regius Professor of Medicine in the University of Oxford. The universal feeling is that His Majesty, King Edward, could not have approved of a more suitable selection for the vacant chair. Dr. Osler commenced his medical studies in Toronto in 1868 and graduated at McGill University, Montreal, in 1872. For many years he was a highly esteemed teacher on the medical faculty at McGill, and when in 1884 he accepted the position of professor of clinical medicine in the University of Philadelphia, his departure from Canada was greatly regretted. He has, however, always taken a lively interest in everything pertaining to the welfare of the profession in this country, and was frequently a guest at medical gatherings in different Canadian centers. His address at the opening of the new buildings for the medical department of Toronto University, last year, was one of the best contributions ever given to Canadian literature. Canada proudly claims William Osler as a gifted son.

The Ontario Medical Library Association is likely to have very shortly a home that will provide what has long been desired in the city of Toronto. A very desirable property has been purchased in the Queen's Park, and is being remodelled and fitted up in a suitable manner. It will not only be well adapted for a library, but will have ample accommodation for society meetings and become a popular resort for medical men. Toronto has long felt the need of a medical club, and the very desirable property which has been secured will without doubt prove a popular investment. There are now over 10,000 volumes in the library and large additions are expected very shortly. The medical men who have the matter in hand are receiving not only the cordial support of the profession in Toronto, but, as that city is regarded as the medical center of Ontario, they have assurances of support from all parts of the Province.

Hon. Dr. Sullivan, of Kingston, who is a member of the Canadian Senate, has been moving in Parliament for stringent regulations in regard to the sale of patent medicines in Canada. He made a vigorous attack on the patent medicine business as a whole, and contended that all makers should be compelled to give the exact compositions of the compound placed on the market; also that all guarantees of cures should be strictly prohibited. He was particularly effective in pointing out the fraudulent character of many of the testimonials published. Senator Sullivan is well supported in his efforts to place restrictions on the patent medicine business. Sir William Mulock, Postmaster General of Canada, introduced a bill declaring that it shall not be lawful to transmit by mail in Canada any books, magazines, periodicals, circulars, newspapers, or other publications which contain advertisements representing marvelous, extravagant, or grossly improbable cures. During the discussion on his amendment, Sir William Mulock said: "It was necessary to put a stop to the methods of scoundrels who advertise marvelous cures and make fortunes out of the unfortunate sufferers." Stringent enactments are likely to soon be enforced in Canada against what has long been regarded as a scandalous misuse, not only of the mails, but also of the public press, for the advertisement and encouragement of quackery.

The Provincial Board of Health for Ontario have just issued a report dealing with tuberculosis and demonstrating the extent to which consumption has prevailed in Ontario and the beneficial results that in later years have resulted from an increased knowledge of the nature of the disease. The death rates from smallpox and typhoid are insignificant compared with it. Tabulated returns for thirty-three years show that the number of deaths from tuberculosis have exceeded those from all other contagious diseases put together by nearly ten thousand. The figures are: Consumption, 75,918 deaths; all other contagious diseases, 66,240. The returns for the other diseases are as follows: Typhoid, 14,558; scarlet fever, 10,372; diphtheria, 31,486; whooping cough, 5,513; measles, 3,213; smallpox, 1,044; typhus, only 14. Typhus occurred in three years, 1869, 1882, and 1883. The variableness of the ravages of tuberculosis is illustrated by the returns of later years, which are interesting. In 1894 the number of deaths from consumption were 3,240; in 1895, 2,427; in 1900, 3,484; in 1902, 2,694. The variableness was probably caused by the climatic conditions, and in later years to some extent the decrease is attributed to the realization by the public that it is a contagious disease, and that to the fight made by sanitary precautions against "the white plague." The figures, however, show what an immense work remains to be done. To accomplish this there is certainly considerable progress being made, and the public press is rendering valuable assistance in the good work. Local boards of health in all parts of Ontario are also taking more active measures in that direction.

The dentists of Canada are in advance of the medical men in their efforts to secure Dominion registration, so that dentists legally qualified in one Province can secure registration that will qualify them to practise dentistry in any of the other Provinces. Faithful efforts have been made for several years to secure a Dominion Medical Act that will secure what has so long been desired by the large majority of the medical men in Canada. At present each Province has a separate and distinct medical registration board and a practitioner in one Province cannot practise his profession except within the limits of his own Province. All the Canadian Provinces, except Quebec, have signified their willingness to have a registration board for the whole Dominion. That one Province should have the power to prevent the act being passed seems to many most unjust. Dr. Roddick, M.P., of Montreal, who has in Parliament taken a very active part in endeavoring to secure the enactment of a law in favor of Dominion registration, has, to the regret of the whole medical profession in Canada, signified his intention of retiring from Parliament. He has proved a most useful parliamentarian, and it is to be regretted that he has not succeeded in having his bill made law. It must succeed at no distant date.

BIOLOGY OF THE TUBERCLE BACILLUS.

To the Editor of the Medical Record,

Sir: I read in your valuable journal of August 20, page 296, an item in which R. W. Philip was quoted to the effect that the good effect wrought by suitable treatment of the tuberculous patient at home by climatic factors in too many instances is undone at night by sleeping in stuffy and overcrowded rooms. He might have added that this same fault occurs at tuberculous sanatoria, where the patient, in too many instances, is allowed to lower his tent sides to exclude the morning air, which the bacillus, like the patient, does not like. The good effects, too, of climatic treatment in summer time are undone when winter comes by too close housing of our patients. When the tent sides are down at night I find patients have a run of fever the next morning; but when they are exposed through the night to the motion of the winds, there is less often fever the following morning. Evidently the bacillus is more quiescent when exposed to the wind. There is also better returns, that is, more improvement, from exposure in winter than in summer. Cold morning air is not liked by the bacillus of consumption. This was my experience with two patients here last winter. And it is also the experience of Devon Sanatorium, in the south of England, and Sanatoria in Norway and elsewhere.

Albert S. Ashmead, M.D.
Greentown, Pike Co., Pa.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Sept. 29, 1904

Disease of the Myocardium.—Henry Jackson states that myocardial disease may arise from various pathological processes: The disturbance may be within the heart itself. Sclerosis of the coronary arteries is in many cases the direct cause of myocardial disease, for with the narrowing of the vessels the nutrition of the heart muscles suffers, and a gradual fibrous degeneration develops. Precordial pain and distress seem to be more common in cases of sclerosis of the coronary arteries than in other forms of myocardial disease. The most common cause of myocardial disease is general arteriosclerosis. The younger the individual attacked, the greater the probability that the heart will be involved. The third cause mentioned is renal disease, especially when the type of the disease is essentially that of a chronic interstitial nephritis. Many cases are seen in which no pathological factor can be found. In another class of cases is noted the excessive abuse of alcohol, but no gross pathological lesions are found. The heart may be enormous in size. Again, there are a few cases without any known etiology. Tumor of the myocardium, in a few rare cases, gives rise to symptoms suggestive of "heart disease." The writer has noticed this condition only in syphilitic myocarditis. These observations are sufficient to show that "heart disease" does not always mean valvular disease of the heart. The writer believes, in fact, from his study of various records and statistics, that valvular disease of the heart is found in only about half of the cases of "heart disease."

Blood Pressure in Fevers, Before, During, and After the Administration of Strychnine.—Richard C. Cabot, in these investigations, has studied febrile cases only, among them being cases of typhoid fever and pneumonia. In 32 cases, the strychnine was given by mouth, and in 18 subcutaneously. The total daily dose was usually ⅛ grain. The records were continued for days, and occasionally for weeks before and after the drug was given, in order that the regular range of variation in the blood pressure might be ascertained. The measures were taken with Stanton's modification of the Riva-Rocci instrument. Measurements were taken at various intervals of time succeeding the administration of the drug, from a few minutes to several hours. The observations extended over about 8 months and included over 5,000 measurements. The writer declares the total result to be negative. A striking feature in these observations was the fact that while whiskey and strychnine seemed to have no influence upon the blood pressure, the sight of food or the prospect of getting up produced a decided though transient rise in the pressure. The only permanent gains in pressure occurred when the patient reached the crisis in pneumonia, or when convalescence enabled him to get up and walk. The writer does not wish to be construed as saying that this drug has no value, but he believes that in the dosage employed, strychnine does not raise or in any way affect the maximum or minimum blood pressure so far as can be determined by the instrument employed.

Earache, or Cases of Early Involvement of the Middle Ear, Usually Neglected.—Francis P. Emerson believes that abnormal conditions in the nasopharynx as a cause of earache are usually neglected until serious damage has resulted to the middle ear. He cites several cases in point. These children all suffered from attacks of earache, and in each case examination of the nasopharynx revealed the presence of adenoids. After the removal of this tissue, the earache disappeared. Catarrhal ears may occur often in children living under the best surroundings. These children may be well nourished and show no evidence of catarrh, nor even be mouth breathers. If the trouble be due to adenoid tissue, this may be found only around the Eustachian tubes and so offer no mechanical obstruction to breathing. This glandular tissue often persists to adult life, especially if it once becomes infected, and it usually exerts a baneful influence upon the hearing. In the case of infection with such active organism as the influenza bacillus, the patient is liable to a rapid involvement of the middle ear and the mastoid.

New York Medical Journal, October 1, 1904.

Mitral Regurgitation.—A general description is given by O. L. McKillip of this variety of valvular affection, following conventional lines. He notes in closing that patients are frequently treated for chronic gastritis when the latter is really a sequel of a heart lesion. The same holds true of pericarditis, but when a murmur is present in the latter disease it is usually a to-and-fro murmur and is not transmitted. There is a murmur heard at the apex due to anæmia. This can be distinguished by the history of the case, the unintensified pulmonic second sound, and the absence of cardiac enlargement. The impulse of the heart against the edge of the lung between the heart and chest wall sometimes produces a cardiorespiratory murmur, but it is heard only at the end of a full inspiration and is not transmitted. So that if we have a murmur at the apex, systolic in time, transmitted to the axilla, an accentuated pulmonic second sound, enlargement of the heart, and evidences of blood stasis, we may safely diagnosticate mitral insufficiency.

Professional Responsibility in Accident Cases Involving Litigation.—J. B. Roberts would divide cases requiring medicolegal investigation into the three following classes: (1) Those in which there is obvious physical lesion of a serious character. Here the surgeon's responsibility mainly concerns prognosis. (2) Those in which a physical lesion is obvious, but manifestly of little importance. Here the question mainly concerns diagnosis, and the surgeon must detect by careful and repeated examinations, evidences of obscure danger to the nervous system or other deep-seated structures. (3) Those of mental shock without obvious physical lesion in which there is a possibility of development at a later period of the so-called functional disturbances to which the term traumatic neurosis has been applied. Here the prime responsibility of the surgeon should be to prevent by judicious treatment the development of the nervous derangement. Many of the nervous wrecks seen in the courts, demanding, and often receiving from juries, large sums of money for accidents, are the creation of injudicious, thoughtless, or dishonest doctors. The author would emphasize two points. First, that an ignorant, careless, or injudicious physician may possibly be the real cause of many cases of traumatic hysteria and neurasthenia; and, second, that prompt settlement of damage suits is an invaluable aid in the cure of accidental injuries associated with litigation.

Headache in Relation to Diseases of the Nose and Nasopharynx.—O. Wilkinson presents a somewhat elaborate summary of the various nasal and nasopharyngeal conditions which may cause headache, and his paper is an elaboration along the lines thus indicated. His list of causes is grouped under the following five heads: Affections of the mucosa, of the osteo-cartilaginous framework of the nose, sinusitis, growths, and foreign bodies. Under the first heading he makes a distinction between hyperæsthetic rhinitis and hay fever, the special diagnostic point being the test with the applicator.

The Fly as a Carrier of Tuberculous Infection.—E. H. Hayward has made observations on flies which were allowed free access to tuberculous sputum. They were then supplied with clean cover slips, which they speedily soiled. Sixteen of the covers, ten of which contained tubercle bacilli, were stained and examined. The next two batches of flies were fed on tuberculous sputum in which the bacilli had previously been demonstrated. The sputum was placed on watch glasses and covered with a fine wire screen. On this screen the fly could walk without getting its feet or wings in the sputum and could feed through the meshes. The flies were also fed on milk, but they seemed to prefer the sputum. Six hours after feeding, clean cover glasses were introduced and left from three to four hours, during which time considerable fæces were deposited on them. They were then withdrawn and stained, and all showed tubercle bacilli. The flies apparently suffered from diarrhœa after feeding on the sputum, as they defecated more after the infectious material was ingested than before. Culture plates, made of the fæces on glycerin agar and incubated two weeks, showed a growth of tubercle bacilli, thus proving that the vitality of the tubercle bacillus is not impaired by passage through the intestinal canal of the fly. Post mortems were made from each batch and smears from the stomach and intestines showed large numbers of tubercle bacilli. The fæces were also rubbed up with sterile water and injected into the peritoneal cavity of guinea pigs which developed tuberculosis. The author believes that these experiments show that the tubercle bacillus may be conveyed from the lung of one person to the alimentary tract of another in the course of a few hours, and this may be a common mode of infection.

Medical News, October 1, 1904.

The Need of Efficient Public Health Work in the Suburbs.—George A. Soper points out some of the difficulties in the way of protecting health. He first emphasizes the want of knowledge which everywhere exists on the subject of hygiene. Even in the better residence suburbs public sanitary questions are often neglected. Private and domestic hygiene are practically unknown in the squalid outskirts of the city. Hygiene is acknowledged to be a neglected factor in education. Not even doctors are always qualified to act as expert advisers with respect to public health measures. A second difficulty is that of enforcing sanitary laws. Then, finally, there is a want of concerted action among different departments of the local government. Energy is needed to discover and correct the sanitary

conditions in the suburbs. There should in most cases be more assistants in this work than are generally provided. Appropriations for this purpose should be adequate. Laboratories for testing water and milk should be established. The dairies and the watershed should be inspected. The suburb should be made healthful, and the public should have the reasons for knowing it to be so. If preventable diseases are prevalent, the facts concerning them should be stated in the monthly report. The garbage question should be solved in a sane and sanitary manner. It would be well for every citizen to collect a library on sanitary topics. Not the least reward of all this care will be the business advantage that will come from the prosecution of a strict and skilful public health campaign. Intelligent people will come to the suburb. With efficient work on the part of the Health Board, life and health will be more secure.

Report of a Case of Obstinate Phosphatic Diathesis Cured by Systematic Dilatations of the Posterior Urethra.—George Theodore Mundorff reports the case of a man aged 38 years. He had had a gonorrhœa some years ago, and was cured in about 4 months. About 5 years ago his business responsibilities were very much increased, and soon afterwards he noticed that he had become very irritable and nervous, and he was passing a large quantity of urine, which he soon observed was of a milky character. He was treated according to the usual methods, and although the general condition improved, the urine was still loaded with phosphates. The prostrate was slightly enlarged. The writer, having observed a few instances of "phosphaturia" in cases of retention of urine due to temporary or permanent paralysis of the bladder, as in hemiplegia and paraplegia, as well as in cases of prostatic hypertrophy, and having observed the effects of the following treatment, gave posterior dilatations of the urethra and with it dilatations of the internal sphincter ani a trial. Dilatations were made once every week, and irrigations of the bladder with a mild boric acid or silver nitrate solutions were made a few days after each dilatation. After a few treatments there was great improvement. The patient recovered his spirits and the urine gradually cleared. Dilatations were kept up for 12 weeks, at the end of which time the patient was discharged cured. There has never been a return of the complaint. A hyperæmic or chronically inflamed condition of the prostatic urethra often causes marked neurasthenic symptoms. The nerve supply of this region is very rich. Any irritation of this region is sufficient to excite functional disturbances of distant organs. The writer asks if it is not possible that the phosphatic condition of the urine is due to some reflex secretive anomaly of the kidney. He thinks that it is fair to conclude that this patient was suffering from some inflammatory condition of the posterior urethra. Local treatment relieved congestion, and restored the muscular tone of the adjacent organs.

American Medicine, Oct. 1, 1904.

Rheumatism in New Mexico.—W. C. Klutz declares that the cases of rheumatism in New Mexico make up a larger proportion of physicians' work than they do in very much damper localities. In the eastern half of the country the average rainfall is less than 10 inches, while the elevation is about 4,300 feet. The writer mentions two factors as being responsible for the frequency of rheumatism: The natural excess of meat eating, because of the scarcity of fresh vegetables, and the marked difference between the day and night temperatures. Tonsillitis is very common in this region, which is interesting in relation to the existence of rheumatism. The writer thinks that the throat affection is due to the wind and dust of the region. In regard to the factor of meat eating, the writer cites a case of a man of 30 years who, although he has been a strict vegetarian for the past two years, has had an attack of rheumatism during the last summer. The majority of patients who come to New Mexico with rheumatism improve at first, but are liable to fresh attacks after some months. Some cases develop the primary attack in New Mexico. The writer believes that the variation between the day and night temperatures, which is 25° or more at all seasons, must be the chief reason for the relative frequency of this disease in such an arid region.

Dust Infection.—Robert Hessler includes under Dust Disease the vague and illy-defined symptom-complexes that are variously referred to or misdiagnosed as "colds," "biliousness," "sick headache," and so on, or as atypical cases of influenza, rheumatism, gastritis, neurasthenia, and the like. Cases of dust disease are to be especially looked for under and separated from recognized diseases in which "rheumatic and gouty diatheses" are concerned, as well as in cases of neurasthenia and hysteria, and in cases in which there are frequent alimentary or respiratory tract disturbances. This affection is most common in crowded cities. It is not found among Arctic explorers and weather observers on high mountains. When these men return home, however, they are attacked again. The cases may be divided into groups, depending upon the part of the body or the organ chiefly affected. If the existence of this affection is kept in mind, many cases with obscure symptoms will be cleared up. There are no marked or recognizable pathological lesions in dust disease. Mucin may play an important part. The causative factor is infective dust. The cause of their discomfort should be pointed out to the afflicted. In some cases no medication will avail, the only relief coming from the change to a better atmosphere. The writer emphasizes the importance of recognizing the influence of a dust-contaminated atmosphere in the production of ill-health and disease in general.

The Present Status of the Etiology of Malignant Growths.—Raymond Wallace says that exceedingly few cases have been recorded of malignancy in the newborn and in childhood, which militates against any theory of direct heredity; a multiplex and varying etiology must seem the most plausible. Intrinsic irritation of the cell-proliferating mechanism in the nucleus may, with the advance of cell chemistry, yield certain autogenous factors; but as extrinsic factors may be summarized, various physical, chemical, and physiological irritations, and the irritations caused by parasitic life, any of which cause an evident disturbance in cell-proliferation, as it were, a loss of equilibrium, which leads to insane proliferation and the consequent formation of neoplastic growths. The degree of malignancy would then depend upon the rate and type of proliferation, and the loss of function and consequent reversion of type in the proliferating cells. The foregoing argument, based upon both clinical observation and pathological data, is offered as a slightly different phase of a much discussed and ever important subject.

Journal of the American Medical Association, Oct. 1, 1904.

Blood Pressure and Pulse Rate as Influenced by Different Positions of the Body.—O. Z. Stephens' experiments have led him to the following conclusions: (1) The blood pressure increases in the brachials from the standing to the head-down positions, inclusively, in the following order: Standing, sitting, left lateral, right lateral, supine, and head-down. (2) The greater the hydrostatic resistance in the upper portions of the circulatory system the greater the increase in pressure when the nervous and respiratory systems are kept normal. (3) An increase of resistance is accompanied by an increase in heart strength; the strength of the heart, therefore, will increase in the different positions in the following order: Standing, sitting, left lateral, right lateral, supine, and head-down. (4) The pulse rate decreases in the same order that the blood pressure increases. (5) The decrease in the pulse rate is a conservative act on the part of nature to protect the heart itself and the central nervous system.

Fatal Poisoning Due to Skin Absorption of Liquid Shoe Blacking (Nitrobenzol).—A case is reported by W. J. Stone. His patient was a young man of twenty-two years, of previous excellent health, who was suddenly seized with faintness, from which he at first recovered, but following which he passed into a state of coma. When first seen by a physician he was found in a state of collapse, from which he could not be rallied. No peculiar odor was noted on his breath. Death ensued between four and five hours after the fainting attack. Subsequent investigation revealed the fact that he had worn shoes to which a liquid blacking had been applied, and it was evident from the appearance of the skin that some of the preparation had rubbed off on the latter. This preparation was proven to contain nitrobenzol. The shoes were put on before the blacking was dry, and it is believed that enough of the poison was absorbed to produce the fatal result. This was attributed to paralysis of the circulating centers, since the heart stopped beating about five minutes before the respiration ceased. [While we have no opinion to offer in this case, we are not convinced that the absorption of so small an amount of the liquid blacking as is mentioned in this case was the cause of death.]

The Etiology of Hay Fever.—D. Braden Kyle discusses in this paper the relation of the chemistry of the saliva and the nasal secretions to diseases of the mucous membrane of the mouth and upper respiratory tract. He notes that the reactions of saliva and nasal mucus, as given by the ordinary litmus test, are misleading, owing to changes occurring after they had been poured out on the surface of the mucosa. Other tests, notably the polariscopic, are more reliable. Kyle has studied the secretions from patients whose fluids presented respectively neutral, hypoacid, and hyperacid conditions. The excessively alkaline condition is observed more commonly in hay fever, although in this disease any one of the three conditions may prevail. To these the author adds a fourth or irregular variety. In a hay fever case with alkaline reaction, remedies are to be given which will bring about an acid or

neutral reaction, or vice versa. Acting on this theory, he has been able to relieve cases resisting all the usual forms of treatment. On this theory the altered secretions are the exciting irritants of hay fever attacks, and not the various pollens, etc., from without. Such a disturbing cause acting on a neurotic patient, with perhaps intranasal lesions, can produce an outbreak of hay fever just as well as pollen, etc., can under the same conditions. In such cases the serum therapy would be unavailing. Kyle's experience with remedies acting on the secretions in the manner described leads him to believe that over eighty per cent. of cases can be relieved and cured.

The Lancet, September 24, 1904.

The Channels of Infection in Tuberculosis of Childhood.—The views of L. Kingsford are based on post-mortem records of 339 cases in children up to 14 years of age. Considering middle ear cases as infected by inhalation, tonsil cases as alimentary canal infection, and remaining pharyngeal cases as doubtful, inhalation accounts for 216 cases, or 63.7 per cent., ingestion for 65 cases, or 19.1 per cent., with a remaining 17 per cent. as of doubtful origin. From these figures the danger from inhalation would seem much greater than that from ingestion of tuberculous material. With regard to the importance of tuberculous milk, however great the potential danger may be, the real danger is in many quarters greatly exaggerated, probably owing to the children not drinking the tuberculous milk of the virulence and in the quantity usually affirmed. Still, whether the danger has been exaggerated or not, the fact that nearly 20 per cent. of the cases of tubercle amongst children in the large towns in England are primarily alimentary makes out a good *primâ facie* case against tuberculous milk, and the author believes it will be shown that one of the chief differences between the conditions of life amongst children at home and abroad which could have any effect in predisposing to primary abdominal tubercle exists in the greater frequency of tuberculous milk in that country. Statistical tables are given showing (1) the ages at death of all the 339 patients and the number at each infected through the different channels, (2) the frequency for each group of cases with which tuberculous lesions were found in the lungs and intestines and the corresponding lymphatic glands and serous membranes, and (3) the foods upon which the children had been nourished.

Some Points in the Prevention of Epidemic Diarrhœa.—T. T. Nash believes that the usual weather of the summer favors contamination of food, especially milk, first and chiefly by flies, and, second, by dust. He believes, further, that the common house-fly is the principal agent in carrying diarrhœa-causing bacteria to food. He therefore regards the following as essentials for lessening the infant death rate in summer: (1) Clean milk supplies; (2) clean towns, with well organized systems of sewage removal, dust collection and disposal, and street watering; (3) clean homes, where sufficient domestic hygiene prevails to understand the importance of clean utensils for food, the covering over of food to protect from dust and flies, and personal habits of cleanliness, and (4) inhibition of fly life.

A Case of Nephritis Simulating Diabetes Insipidus.—J. B. Blaikie's patient was a girl of eleven years, complaining of thirst and of passing an excessive quantity of urine, the average being 90 ounces, with gravity of 1,003 to 1,006, neutral or faint acid reaction, a faint trace of albumin, no casts and no sugar. Ten days later the quantity and the output of urea (previously about 200 grains per day) diminished, and the patient passed into a nervous condition, ending in unconsciousness, wide but unequal dilatation of the pupils, weak pulse, sub-normal temperature, and Cheyne-Stokes breathing. Autopsy revealed the following condition in the kidneys: The left weighed two ounces and the right three ounces. Both were extremely small; the capsule of each was adherent; the surface was somewhat irregular and showed extreme waxy pallor. On section the cortex was enormously diminished, especially in the left kidney, so as to constitute a mere line at places, with pyramidal cortex also diminished, but to a less degree. The whole kidney surface was of somewhat translucent yellowish-white color, with only a few points and streaks of congestion at places. There were numerous small cysts present both in the cortex and in the medulla; these were more numerous in the left than in the right kidney. The Malpighian bodies appeared enlarged in places. The condition was chronic nephritis with extreme contraction and atrophy, probably following acute and subacute changes. The extreme anæmia of the kidneys was very striking. No waxy change was present.

British Medical Journal, September 24, 1904.

The Protective Value of Proteids and their Decomposition Products in Trypsin.—H. M. Vernon, in discussing the protective value of veinous substances upon trypsin, states that as a rule the protective value depends almost entirely upon the power the substance possesses of neutralizing the alkali and so rendering it incapable of reacting upon the ferment. Most proteids have practically the same protective value, about 45 per cent. of the trypsin of an extract being destroyed each hour in the presence of 0.4 per cent. of proteid, 27 per cent. in the presence of 1 per cent., 12 per cent. in the presence of 2 per cent., and 7 per cent. in the presence of 4 per cent. of proteid. When no proteid was present 56 per cent. of the ferment was destroyed. Hydrated proteids have a slightly greater protective value than native proteids, and the decomposition products of proteid hydrolysis a slightly greater one still. In certain cases there is a combination between ferment molecule and proteid. For example, egg albumen has a very marked antipyretic action, the digestive power of the ferment being reduced to 29 per cent. and 2.9 per cent. of its normal value in the presence of 0.05 per cent. and 1 per cent. of the proteid respectively.

Some Points in the Metabolism of Diabetes.—A. P. Beddard and E. I. Spriggs report some observations concerning this subject. The bad effects such as nausea, vomiting, weakness, loss of weight, with the odor of acetone in the breath, which follow a too rapid withdrawal of carbohydrate from the food of a severe diabetic, are associated with exactly the same metabolic changes and symptoms of acid poisoning as in coma itself. The most striking result in the urine is a rapid rise in the proportion of ammonia. The alkalinity of the blood falls, and the amount of carbon-dioxide in it is diminished. The injurious material does not seem then to be derived from carbohydrate. The spontaneous recovery which usually occurs is accompanied by a diuresis, but not by a fall in the proportion of ammonia. The administration of alkali produces the opposite effects to a diabetic diet as regards the ammonia, and causes a general improvement in the patient's condition and a disappearance of the odor of acetone. Although an increase in the quantity of urine follows, there is no marked rise in the excretion of sugar after the first day or two. It seems advisable to use this drug when a patient is being changed from an ordinary diet to one which is poor in carbohydrate, and especially to a rigid diabetic diet. The object of the alkali is attained when the urine becomes neutral. Its administration must be watched, as disturbances of digestion, diarrhœa, and œdema may be produced. Opium was followed by a diminution in the amount of urine and of its constituents, but not in the proportion of ammonia. Codeine did not appear to produce any effect on the metabolism. The odor of acetone is greatest on a diabetic diet, and is diminished by alkali. This sign and the patient's weight seem to be better guides to the condition of severe cases than is the amount of sugar in the urine.

The Reservoir Action of the Liver.—R. N. Salaman divides the nutmeg liver into three types: The liver of acute congestion with no structural changes, the liver of chronic equable back pressure as seen in tricuspid stenosis, and the cirrhotic cardiac liver where central fibrosis is well developed. The writer has diagrams pointing out the amount of expansion of which the normal as well as these three types of liver are capable under pressure of 1 ft. and 2 ft. 3 in., respectively. These diagrams demonstrate that whereas under 2 ft. 3 in. the normal liver doubles itself, the congested and chronic nutmeg livers expand to only about one and a half times their volume or less; while the cardiac cirrhotic liver is capable of but little expansion. It is shown that the conditions of œdema and ascites in heart disease depend directly upon the histological condition of the liver. So the liver can be looked on as a safety-valve to the right heart which by continued use loses its value and shortens greatly the field of cardiac response.

Rigor Mortis in Stillborn Children.—C. H. W. Parkinson concludes that (1) Rigor mortis may occur *in utero* and (*a*) may pass off before labor terminates, or (*b*) may occur during, and so hinder labor and continue after delivery. (2) In death during the later stage of labor, when the child is expelled soon after death, rigor mortis may set in afterwards. (3) In all cases of stillbirth the character of the rigidity is the same, and whereas in children that have been born alive the rigidity is that of ordinary rigor mortis, and the limbs stiffen in the position in which they may be then lying, in children stillborn the rigidity always takes the same form, and the limbs, although lying loose and limp, are drawn up more or less into the position they took in the uterus; and even if the rigor mortis had passed off *in utero* before delivery, there would be evidence by pressure-marks, or the natural tendency of the body and limbs to adopt the intra-uterine position, that this has occurred. (4) Rigor mortis does not accompany stillbirth always, but when it is not present there is no difficulty in deciding the fact from the signs of decomposition present. The mode of death probably influences the rigidity in stillbirths as it does the rigor mortis of adults, and the only

suggestion the writer can make is that possibly the rupture of membranes and discharge of liquor amnii may be a factor. The important point is that in a case of suspected infanticide, or when there is a question of live birth, any evidence that the limbs and body have been drawn up while in a state of cadaveric rigidity into the shape in which the body is moulded *in utero* is a strong evidence of stillbirth.

Berliner klinische Wochenschrift, September 5, 1904.

Examination of the Gastric Contents in the Aged.—H. Saidelin has made a series of investigations for the purpose of determining whether achlorhydia was normally present in elderly persons. Gastric cancer is most frequently found at this time, and in making a diagnosis of this condition, a great deal of importance has been attached to achlorhydia as a symptom. It is possible, however, that in the aged this cannot be taken into account. The author made analyses of the gastric contents in a large number of patients over 50, who were suffering from some disease not connected with the stomach. He found that even in advanced age the secretion retains its usual characteristics and is very slightly weakened. In a comparatively large number of cases an achlorhydia exists and there seems to be some connection between this and arteriosclerosis, but this cannot as yet be explained. The practical conclusion is, that in elderly persons care must be taken in ascribing any diagnostic significance to achlorhydia as a symptom.

Treatment of Chronic Joint Disease by Bier's Method.—A. Laqueur reports on an extensive series of cases of rheumatic and gonorrhœal joint disease in which the artificial production of a venous hyperæmia was employed. The results in all cases were excellent, when the method was used alone or in connection with other physical procedures. The author believes that the method deserves more universal recognition in this class of cases, as it has been proved to be of value and, moreover, is simple and cheap. The anodyne effect is very well marked.

Ptosis of the Abdominal Aorta.—Stiffler calls attention to the part which the abdominal aorta takes in the presence of ptoses of other organs in the cavity. These cases are usually severe ones, and the recognition of this condition is important in the treatment. The changes ordinarily take place in the space between the diaphragm and the transverse mesocolon, and of these the author describes two forms. The aorta may be uniformly dilated up to twice its normal size, and may be palpated from the navel upwards along the course of the gastrocolic ligament. The other is the contractile form, in which the vessel becomes reduced in size and elongated, giving it a tortuous course. It may be felt on either side of the median line as a sharply pulsating vessel. Ptosis of the aorta is usually a complicated ptosis, and when there is no reason for assuming that a congenital or an atonic disposition exists, it must be attributed, according to most writers, to traumatic and mechanical influences. The contractile form is brought about by the irritant effect of inflammatory scars and proliferations starting from the mesogastrium (gastritis, gastric ulcer), the mesœcum (appendicitis), or a para- or perimetritis. The conditions which particularly favor the development of this ptosis are relaxations resulting from gynecological or surgical procedures, various 'cures' (anti-fat, water, massage, etc., carried to extremes), paralysis agitans, hysteroepilepsy, and improper modes of correcting movable kidneys by unsuitable apparatus. The disturbances attending ptosis of the aorta are largely functional in character, such as interference with nutrition, central and vasomotor trophic neuroses, hypersensitive reflexes, and the syndrome of symptoms designated as the neurosis of the cœliac plexus, which are described by the writer in detail. A number of typical cases are reported by the author, who states that in about half the cases of general ptosis coming under his observation a ptosis of the aorta was present.

Münchener medizinische Wochenschrift, September 6, 1904.

Paroxysmal Hæmoglobinuria.—Donath and Landsteiner present an elaborate account of the status of this subject, and as the result of their studies, supplemented by experiment, they have arrived at the following conclusions. In paroysmal hæmoglobinuria, hæmolysis is due to the absorption of a toxic substance contained in the serum of the patient. The blood cells absorb this substance and become dissolved in the serum not only of the hæmoglobinuric patient, but also in other human serum. This solubility is aided by the complements of the serum (alexin, cytase, etc.).

Icterus and Diabetes of Nervous Origin.—Rheinboldt states that, although there is an acknowledged connection between the nervous system and these conditions, a clear picture of such relations has not yet been presented on account of the difficulty of the subject. A case in which there was a combination of icterus and glycosuria is reported by the writer as occurring in a woman of fifty who was of a nervous temperament. She was subjected to sudden attacks of irritability which were accompanied by typical transitory jaundice, and during one of these a glycosuria was also detected. The attacks came on within a few hours after one of her nervous spells began, and disappeared as quickly. Diet had no effect on the glycosuria. The author discusses the etiology of such a condition as presented by various writers, and believes that the association of the two points to a nervous influence exerted on the liver.

Deutsche medizinische Wochenschrift, September 8, 1904.

Treatment of Chronic Empyema of the Antrum of Highmore.—P. L. Friedrich discusses the severer types of empyema of the antrum and presents the results of his methods of treatment in this class of cases. As the excessive foul secretion furnishes the main indication for treatment, means of getting rid of it have necessitated laying open freely the cavity from which it is derived. Friedrich claims that this can only be done by resecting the anterior wall and, in addition, it is essential that sufficient communication be established into the nasal cavity on a level with the floor of the antrum. A flap is made which includes the ala nasi close to its base, the incision about two cm. long being carried down to the bone. From the middle of this another short incision is carried downward and outward. The flaps are reflected and the intervening soft parts down to the crista are displaced, until this bone is thoroughly exposed. The crista and 1 square centimeter of the anterior wall close to the floor of the antrum are removed, together with a part of the inferior turbinate bone if this is in the way. This freely exposes the antrum, which may be readily explored and cleaned out. A tampon is then introduced which leads out through the nose and the external wound is closed. Healing takes place promptly within a comparatively short space of time. Seven successful cases are reported.

Infection by Ankylostonum Larvæ Through the Skin.—F. Schaudinn has made animal experiments for the purpose of deciding whether this can occur as claimed by certain writers, but never definitely proved. A number of monkeys were inoculated with the larvæ of the ankylostomum and after death the worms could be demonstrated not only in the small intestine, but also in the thorax and various vessels. This seems to confirm the statement made by Looss, that invasion of the body may take place in this fashion.

Amyotrophic Lateral Scelerosis After Trauma.—O. Giese comments on the rarity o fthis condition and says this accounts for the little we know about its etiology. Among others, trauma has been described as a causative factor, and an instance of this is reported by the author. A man of 39 was subjected to a severe fright in a machine accident, after which he was unconscious for several hours. It was later noticed that the man grew morose, and although apparently well, became unable to work and complained of being constantly tired. Some time later he had another accident and hurt his arm, after which he noticed an inability to use the limb. Examination of the patient resulted in a diagnosis of multiple neurosis. The man grew worse and finally presented the picture of an amyotrophic lateral sclerosis. The writer thinks that the trauma can only be considered a causative factor in so far as it brought about the development of latent possibilities. In this case they were probably a congenital or hereditary weakness of the motor nervous system, which was aggravated by the shock attending the injuries.

French and Italian Journals.

Retroperitoneal Abscess of Appendicular Origin.—J. Vanverts gives a history of this case. The patient was a woman of 25 years. Four years before this attack, and again two years later, she had been ill with appendicitis which had been treated medically. This present attack appeared to develop like the preceding ones. The patient sat up for the first time fourteen days after the beginning of the crisis, and the pain and other symptoms—vomiting, fever, rapid pulse—reappeared, as did also the swelling in the region of the appendix. These symptoms had almost disappeared under medical treatment. The swelling was not, properly speaking, in the right iliac fossa. It was rather high up, reaching nearly to the costal border, and extending backward into the lumbar region. The diagnosis of periappendicular abscess was made, and the abscess was opened by the extraperitoneal route. There was an abundant outflow of pus without any special odor. After this, general improvement was rapid. Five days later the pus had the odor of urine. This odor became stronger, and soon the urine escaped from the wound, the quantity of pus being insignificant. Twenty-four days later, catheterization of the ureter showed the canal to be free. The catheter, which was left in the ureter, drained the kidney perfectly for twenty-four hours, although the lumbar drain remained

in place. Then the catheter became obstructed and the flow of urine reappeared at the lumbar fistula. The ureteral catheter was removed, and the lumbar drain was shortened, and on the next day was removed. The urine, at first purulent, cleared up rapidly. The recovery is perfect, it now being eighteen months since the attack. After carefully studying the case, the writer believes that the abscess was of appendicular origin. The abscess was not, properly speaking, periappendicular, but the condition was rather one of para-appendicitis. This para-appendicitis was primary and not consecutive to a periappendicitis. The development of the urinary fistula was secondary to the surgical opening of the abscess.—*Journal de Chirurgie et Annales de la Société Belge de Chirurgie,* May, 1904.

Physiological or Ligamentary Hysteropexy.—J. A. Doléris deduces the following conclusions from his study of this subject: The immediate or direct fixations of the uterus are antiphysiological operations, based on pathological principles,—adhesions, deviations, torsions, and forced and abnormal flexions of the uterus, etc. The indirect or ligamentary fixations conform to physiological exigencies. From the point of view of various possible complications, and of results, the first method is bad or at least uncertain. The results of the second are decidedly superior. From the point of view of parturition, reports and statistics agree in condemning the direct fixations. The indirect fixations, the Alquié-Alexander operation, and the intraperitoneal shortening of the round ligaments, have shown only one case of dystocia, in 177 accouchements which have been reported. This double technique —the inguinal and abdominal route—is satisfactory in all cases of retrodeviation, whether simple and reducible, or adherent and complicated. It is not sufficient to replace the retrodeviated uterus and to fix it in a position of normal anteversion; it is necessary, according to the exigencies of the case, to supplement this by plastic operations on the cervix and vvagina, and by restoration of the pelvic and perineal floors.—*La Gynécologie,* August, 1904.

Chlorosis and Tuberculosis.—Marcel Labbé gives an interesting résumé of his observations in the care of such cases. He believes that the teachings of Landouzy, that chlorosis is not a morbid entity, are correct, and that, if it sometimes appears to develop spontaneously, it is simply due to the fact that the cause has escaped the observer who has used imperfect methods of investigation. Of all of the causes which may give rise to an anæmia presenting the clinical symptoms of chlorosis, none is more important nor more frequent than tuberculosiis. The author declares that the following factors—the observation of patients, the persistent search for etiological factors, the history of tuberculous patients from the period of puberty, the history of chlorotic cases, and the employment in these cases of the modern methods used for the diagnosis of tuberculosis, have led him to determine the close relation existing between chlorosis and tuberculosis, and to believe that a very large number of cases of chlorosis are only a form of incipient tuberculosis. He then gives the history of several cases of this nature which show without question the relation between these two affections.—*La Presse Médicale,* August 31, 1904.

Contribution to the Pathological Anatomy of the Pancreas.—Giovanni Ghedini has examined the pancreas in 200 cases of disease of this organ in the laboratory of the University of Turin; the lesions were degenerations, inflammations, circulatory changes, and new formations. Fatty degeneration was frequent in tuberculosis, cirrhosis, cardiac diseases, and pulmonary affections. In these cases the connective tissue had become transformed into a loose reticular tissue, the spaces being filled with large drops of fat; the glandular elements were separated and infiltrated with fat. Atrophy was found in only four cases of diabetes; the organ was much reduced in size, the elements being infiltrated with fat globules, without nuclei, and some of them in a state of necrosis. The author regards this condition as due to poisoning combined with nerve conditions, determining a loss of function of the organ and an absence of glycoinhibitory secretion in the pancreas. Parenchymatous degeneration was frequent in nephritis, in infective diseases, and in pyæmia and septicæmia. In such cases there were fine granules or fat drops in the cytoplasm of the gland cells. Interstitial inflammation, diffuse and chronic, was observed. The increase of connective tissue was localized about the lobules, the islands of Langerhans, and the excretory canals and vessels. This increase is a result of a slow, reactive change following toxic and chronic inflammations. Tuberculous degeneration of the pancreas was observed in 30 cases. Of circulatory disturbances the writer noted hyperæmia, thrombosis, and small hemorrhages. Of new formations there were one small primary adenoma and several secondary sarcomata. The author also made experiments to prove the origin of the fat in the pancreas, and concluded that it is absorbed by the lymphatics, circulates in solution, enters the cells and transforms them. He also experimented by producing a toxic glycosuria in animals by injections of drugs. He found that the pancreas alone was affected. The glycolytic or glycoinhibiting secretion of the pancreas was diminished or abolished, and glycosuria resulted.—*La Riforma Medica,* August 23, 1904.

Pathological Histology of Chronic Oöphoritis.—Carlo Pinto has made histological examinations of 23 ovaries, in 12 cases of chronic oöphoritis operated on in the hospital at Dresden, of which he gives the details. The alterations of the stroma vary; in some there is a simple hyperplasia of the connective-tissue elements, while in others the alteration is so complete that the substance looks like a mass of connective tissue. In other cases the cortical zone shows all the follicles atrophied and changed to connective tissue. The blood-vessels show a hyaline degeneration of the intima and media, and a small celled infiltration around them. There is a vascular hyperæmia, especially about the follicles, and hemorrhagic foci in the stroma are numerous. In the parenchyma the germinative epithelium is often lacking; in some cases the epithelium dips down into the substance so as to form small cysts lined with epithelium. Of the primordial follicles the number is much diminished. The Graafian follicles in process of development are also few in number. The development of the follicles is interrupted by the inflammation, and atresia ensues. There are often perifollicular hemorrhage and alteration in form of the follicle. The cells of the membrana granulosa are the subjects of granular degeneration, and contain vacuoles. The germinal vesicle has disappeared in many cases entirely. The author ends by classifying chronic oöphoritis as follows: 1. Chronic diffuse oöphoritis, in which the pathogenic agent enters by the vessels of the hylum, in which the whole substance, stroma as well as follicles, is involved. 2. Chronic cortical oöphoritis, in which the pathogenic agent enters by the external surface of the ovary, involving the cortical portion, follicles, and stroma. 3. Microcystic degeneration is to be considered as a chronic inflammation of the ovary, giving a third form. 4. No matter how great the cystic alterations of the ovary, some part is preserved so as to carry out its function normally.—*Archivio di Ostetricia e Ginecologia,* June and July, 1904.

Rectal Electric Cataphoresis.—Tommaso Grossi has conducted experiments on dogs as to the effect of the electric current on the absorption of drugs from the rectum. He injected into the rectum solutions of three drugs, applying within the rectum the positive pole or the negative pole of the battery, so as to ascertain which pole had the greater effect. From his experiments he concludes that drugs are more promptly absorbed in presence of the electric current than without it; that the action of the negative pole is greater than that of the positive pole; and that the drug is absorbed in greater quantity and remains longer in the organism. He considers this as a fair example of the effect of electric cataphoresis on the mucous membranes of the body.—*Giornale di Elettricità Medica,* September and October, 1904.

American Journal of the Medical Sciences, September, 1904.

Aphasia and the Cerebral Zone of Speech.—Charles K. Mills defines the cerebral zone of speech as including an extensive cortical region, probably not less than one-third of the cortical expanse of the lateral aspect of the left hemicerebrum. Both the cortex and subcortex of the entire region enter into its formation. The auditory center for speech is situated at the junction of the first and second temporal gyri about opposite the point where the horizontal branch of the Sylvian fissure turns upward posteriorly; the dynamic or motor speech centre occupies the hinder part of the subfrontal or third frontal convolution, and according to the views of the writer, the insula or at least its anterior half; the visual centres immediately concerned with speech are located in the angular gyre; the site of the graphic or writing centre is in the caudal half or third of the second frontal convolution, and the naming centre is probably situated in the third temporal convolution. Connecting these centres with each other, and also with other parts of the brain, are subcortical tracts. Surrounding the language zone on all sides are centres and areas which have important relations to the function of speech. The writer presents a series of personal observations demonstrating the existence of the centres of the language zone. He believes that Broca's convolution and the insula (perhaps only its anterior part) constitute conjointly the same speech centre, a large cortical area being requisite for that part of the speech mechanism which is represented by this region. He believes that neither of these areas has projection fibers. Here language is organized for the use of the facial, lingual, and laryngeal centres situated anterior to the foot of the central fissure. The writer has long believed in the existence of a separate graphic or writing centre situated in the second

frontal convolution. The two classes of cases which prove the existence of such a centre are those in which a lesion absolutely circumscribed to Broca's convolution, or the insula, or both, causes aphasia without agraphia, and those in which a lesion circumscribed to the alleged position of the graphic centre in the second frontal convolution causes agraphia without aphasia. He has seen two such cases. Short association fibers connect the speech centre with the true motor centres for articulation and enunciation. As to the auditory centre for speech, or the word-hearing centre, it is, as mentioned before, at about the junction of the first and second temporal convolutions. The writer believes that in the cerebral cortex are situated primary auditory and visual centres, and indeed primary centres for all of the forms of sensibility, special and more general, as for cutaneous sensibility, smell, and taste. Each centre has around it its sphere of influence, as it were, which in the case of the auditory centre is a large area concerned with all forms of what might be termed object-hearing. The correlation of the cerebral zone of speech with the sensory and motor regions of the brain is illustrated by those cases of mixed sensory and motor aphasia which are often seen.

Borated Food as a Cause of Lesions of the Kidneys.—Charles Harrington states that borax and boracic acid are the two most commonly used chemical preservatives of food. They are added to milk, butter, oleomargarine, and some forms of cheese; they are nearly always present in opened clams and oysters; they are applied externally to fresh meats to prevent sliminess, and to fresh and salted fish; they are in the brine in which meats are pickled and corned; their solutions are injected into hams and other pork products; they are in almost every known make of sausages. As much as .87 per cent. of boric acid has been found in canned sausage, and even 2.8 per cent. in canned crab meat. American corned beef has been known to contain 3.87 per cent. Once established in the tissues, it cannot be soaked out or even boiled out. Certain individuals cannot undergo borax or boric acid medication any better than others can take quinine or morphine. The most striking effects of borax come not from metabolism experiments but from its therapeutic use. The medicinal use of borax is not unattended with risk of producing or aggravating lesions of the kidneys. The writer, in experiments on cats, showed that in all but one, fed on borax, there were produced lesions of the kidneys. The lesions were analogous to those found in subacute and chronic nephritis in man. The writer shows how by taking ordinary food, a person might swallow upward of 7 grams of borax and boric acid in one meal.

A Case of Suture of the Heart, With Recovery.—Francis T. Stewart reports this case. The patient was a colored man, twenty years of age. He was stabbed, the knife having wounded the heart. The writer, after exposing the wound, closed it with a continuous silk suture. Afterwards, the pericardial wound was sutured, a small opening being left for a gauze drain. On the thirty-fifth day, the patient was allowed out of bed. The writer appends a table of reported cases. The dangers of the drain are the same in these cases as elsewhere—infection and adhesions. Of the twenty-two cases in which the pericardium was drained, two died within a few hours, and of the remaining twenty, ten (50 per cent.) recovered. Of the fifteen in which the pericardium was closed without drainage, one died in fifteen minutes, and of the remaining fourteen, seven recovered. The question may still be regarded as an open one. Of the twenty-three cases that recovered after operation, eleven are known to have been complicated with some form of infection. In only one case is uncomplicated recovery stated.

Symptoms and Diagnosis of Pericarditis.—David Riesman declares that pericarditis is, as a rule, more damaging to the heart than endocarditis. The principal features of this affection are, first, the friction sound. This is most marked in acute fibrinous pericarditis, the commonest form. Its site of maximum intensity is to the left of the sternum in the third and fourth interspaces, and sometimes in the second. It is usually of a churning character, superficial, and markedly intensified by pressure with the stethoscope. When the friction sound is loud it is often difficult to distinguish endocardial murmurs. Pain and tenderness are often present. The pain is sometimes intense. As to the apex beat, in the fibrinous form, the apex impulse is diffuse, indistinct, and sometimes undulatory. In effusions of any size it is commonly absent. When it can be located, it is found above the lower level of dulness. Few conditions are more often overlooked than effusion into the pericardial sac. Pericardial effusion sometimes simulates mediastinal tumor. Pericarditis with effusion sometimes simulates pneumonia. Morbid conditions in the chest may cause pain to be referred to the abdomen. Fever, as a rule, is present in acute pericarditis. Mental disturbance is not rarely observed. Adherent pericardium probably more often than any other important condition, comes to the autopsy table undiagnosed.

Two Cases of Paracentesis of the Pericardium.—John B. Roberts cites these cases. The first patient was a colored woman suffering from pericarditis and bronchopneumonia. She was tapped in the fourth left interspace over the apex beat. Three ounces of a very bloody serum were drawn off. The wound was sealed with collodion and cotton. The woman breathed more easily and had a better pulse. Three days later, another puncture was made, and 4½ fluidounces of dark, bloody fluid were obtained. The patient died the next day. The second patient was a colored man aged thirty-one years. He was sitting up to breathe. The writer tapped in the fourth right interspace close to the sternum. Three fluidrachms of slightly reddish fluid were obtained. The next day the patient seemed better. In two days he died. Autopsy showed no pleural effusion, no fluid in the pericardium, but a marked amount of lymph in the pericadium. The heart was greatly hypertrophied.

Varieties of Splenic Anæmia.—Alfred Stengel reports five cases as a contribution to the knowledge of the condition generally designated as splenic anæmia. He declares that analysis of the clinical descriptions and pathological features of many of the cases classified as splenic anæmia discloses the fact that these cases properly belonged to progressive pernicious anæmia or intense secondary anæmia. Strümpell's oft-cited case belongs to this group. It was probably a case of pernicious anæmia in which there was simple congestion of the spleen with great dilatation of the splenic sinuses. In the conditions now classified as splenic anæmia impoverishment of the blood is rarely a predominating feature, except after repeated hemorrhages. It was once thought that pseudoleukæmia was generally a splenic variety of Hodgkin's disease. It has been shown that splenic pseudoleukæmia may be clinically nearly if not quite identical with that now called splenic anæmia. Such cases are, however, exceptional. Some writers regarded splenic anæmia as an aleukæmic variety of splenic leukæmia. There is an occasional subsidence of leucocytosis in leukæmia. Some degree of splenic enlargement is habitual in cirrhosis of the liver. The cirrhotic process may be demonstrably secondary to the splenic disease. Then the condition is rather one of splenomegaly with cirrhosis. Some of the cases of familiar splenic anæmia in particular may perhaps be more properly classified as hypertrophic cirrhosis of the liver. Great confusion exists in the case of chronic splenitis, or splenic enlargement in children. This enlargement is common in rickets and congenital syphilis. How far malaria may prove to be a factor in the etiology of splenic anæmia remains unsettled. At present it would be hopeless to attempt a classification of all reported cases. More careful study must be given to these cases. And it must be recognized that the long continuance of the disease may cause very different lesions at different stages. The writer mentions the following varieties, which may be recognized provisionally: simple splenomegaly, simple splenomegaly terminating in cirrhosis of the liver, splenomegaly with marked constitutional disturbances, and primitive splenomegaly. It is perhaps not possible to distinguish this last variety clinically, but there is a sharp distinction in the pathological features. The essential characteristic of this condition is the presence of irregular oval spaces surrounded with fibrous tissue and more or less filled with large endothelial cells containing one or more nuclei.

Ascarides in the Bile-Ducts Simulating Gallstone Seizures.—A. M. Pond states that able investigators have observed that when the flow of bile along the ducts is for any reason arrested, microorganisms usually invade the gall-bladder. Charcot and Gombault first demonstrated this fact by ligating the common duct in dogs. Mayo-Robson gives three possible sources for the bacteria: They may reach the gall-bladder through the bile-ducts, from the blood, or directly through the wall of the gall-bladder. It is only in diseased conditions that these microroganisms are present in the bile. It seems that the biliary apparatus will tolerate a moderate degree of inflammatory involvement, providing the flow of bile is not interfered with, but cannot withstand the closure of the chief duct and resist the invasion of the bacteria. The writer reports an interesting case in which the patient was deeply jaundiced and suffered from attacks of severe colic, lasting a few hours, leaving a sense of soreness in the epigastrium. The diagnosis was that of probable impacted gallstone in the common duct. Within a few days a live ascaris lumbricoides 28 cm. long was found in the stools. Santonin with calomel was ordered, followed by castor oil. In a few days the pain subsided, the liver area of dulness became normal, the jaundice gradually faded, and the patient was discharged.

Book Reviews.

Estudio del Pie Plano. Por el Dr. D. Saturnino G. Hurtado. Profesor de Ortopedia y Enfermedades de los Huesos y Articulaciones del Instituto Rubio. Madrid: Enrique Teodoro, 1904.

This monograph contains the results of a profound study of the mechanical causes of flat foot and an exposition of the author's mode of treatment, based upon his conceptions of the causal conditions.

Contributions from the William Pepper Laboratory of Clinical Medicine. University of Pennsylvania. (Reprints.) No. IV. Philadelphia.

This pamphlet gives evidence of the excellent work being conducted by a laboratory in close touch with clinical cases. Histories, necropsies, chemical analyses, etc., which would serve to clear up mooted questions are here described by those specially competent and make interesting and instructive reading.

Arquitectura del Aparato de Sustentación en los Vertebrados. Por el Dr. D. Saturnino Garcia Hurtado. Madrid: Idamor Moreno, 1904.

This is a well-reasoned essay on the vertebrate skeleton and the mechanical forces effective in the bony architecture, together with the actions of those forces in the normal human skeleton, and the application to orthopedic surgery of the facts here developed. The author has made a deep study of his subject and his conclusions are interesting and most practical.

The Medical Epitome Series: Surgery. By M. D. Magee, A.M., M.D., and Wallace Johnson, Ph.D. Philadelphia and New York: Lea Brothers & Company, 1904.

This little book is an endeavor to present in compact form the essentials of modern surgery, mainly for the use of medical students. The text is written in a concise style and there are many familiar illustrations. In previous series of this kind, questions were interspersed through the text, but in the present edition they follow each chapter, thus permitting continuous reading without interruption. The book forms a handy quiz compend in preparing for college or State Board examinations.

The Student's Handbook of Surgical Operations. By Sir Fred'k Treves. New Edition, revised by the author and Jonathan Hutchinson, Jr. Chicago: W. T. Keener & Company, 1904.

This book is intended for students preparing for final examinations or as an aid in carrying out operations on the cadaver. It is abridged from the same author's large "Manual of Surgery," and concerns itself with the most essential and commonly performed operations. General principles and critical considerations of the value of the various methods have been omitted. A description of the anatomy of the region, instruments, the subjects of mortality and results, have all been left out, as have the operations of minor surgery. The prominence of the author in the field of surgery will insure to the book a favorable reception.

A Course in Qualitative Inorganic Chemistry. By A. L. Green, Ph.C., M.D., Ph.D., and C. E. Vanderkleed, Ph.C., B.S., A.C. Fourth Edidtion. Lafayette, Ind.: Arthur L. Green, 1904.

This work is the outcome of the authors' personal experiences in teaching inorganic chemistry and this edition is the first to be prepared for use outside of their own class room. The book is written in schematic form and is intended for a laboratory guide. The experiments are arranged in such a manner that the student is prevented from following the text in a mechanical way. The authors believe that chemistry affords a good training in logical thinking and have therefore arranged a goodly portion of the text in syllogistic form. A thumb-index gives ready access to various parts of the little book and in an appendix are contained directions for teachers based on the methods adopted at Purdue University by the authors.

Physician versus Bacteriologist. By Prof. Dr. O. Rosenbach, of Berlin. Authorized Translation from the German, by Dr. Achilles Rose. New York and London: Funk & Wagnalls Company, 1904.

Although but few American readers will agree with the sentiments expressed in this volume, still they cannot fail to learn much and to admire the courage of the author in thus attacking theories which are accepted by the majority to-day. There is no doubt that bacteriology needs some checking when it crowds out clinical experience from having a balancing influence. The author points out many of the fallacies and weaknesses of accepted doctrines and it would be well if the bacteriologists should read his arguments, if for no other reason than to explain and refute. The book really consists of the articles written during the last decade and immediately before and is arranged chronologically, showing that many of his earlier warnings, when bacteria were beginning to be considered the only cause of disease, have at last been heeded in part. Much, however, to which the author objects seems at this time firmly established, especially the universal acceptance of serum therapy in certain diseases.

Tratado de Ginecología. Por Miguel A. Fargas, Catedratico de Obstetricia y Ginecologia de la Facultad de Medicina de Barcelona, etc. Tomo I, Fasciculos I y II, Barcelona: Salvat y Ca, 1904.

This work, the first volume of which includes general considerations and diseases of the vulva and vagina, is an exhaustive treatise on gynecology, in general scope and appearance suggesting Kelly's well-known book. The author is one of the foremost representatives of modern gynecology in Spain, and is thoroughly up to date and cosmopolitan in his views, a careful and studious reader, a keen observer, and an experienced clinician. He presents his subject with thoroughness and a talent for detail without unnecessary diffuseness, in a clear, systematic manner, making the book in the best sense a textbook. Credit is given wherever due to American observers, which is more than can be said of some foreign books. As regards indications for operations the author is very precise and moderately conservative, representing in his position the latest views of gynecology as practised in the great clinics of Europe and America. He strongly opposes indiscriminate operating, as indulged in by those who have been blinded by the comparative immunity from danger resulting within the last decades from improved technic, but he is apparently heart and soul in operative work, when needed. In description of technics he shows especially a mastery of the subject which places the book in the front rank of treatises on modern gynecology. The book is well got up, profusely illustrated, and will appear in two volumes.

Chirurgie Orthopédique. Par le Professeur Paul Berger et le Docteur S. Banzet, Chef du Laboratoire de Médecine opératoire á la Faculté de Médecine de Paris. Paris: G. Steinheil, 1904.

This is a volume of 624 pages, illustrated by 483 figures, most of which are borrowed from other sources. It is divided into three sections, in which are considered deformities of the trunk, of the upper, and of the lower extremities. In this work, orthopedic surgery is regarded as limited to the treatment of actual deformity. For example, it is stated in the introduction that the treatment of the distortions caused by diseases of the bones and joints is considered in detail, but that the treatment of the diseases themselves will be found in another volume, as yet not published.

This antiquated classification by which effects are separated from causes renders the book quite inadequate as an independent text-book. Within its limits, although it contains nothing particularly original, it is fairly complete. The descriptions of various operative procedures, particularly those of plastic surgery, are well illustrated and are perhaps the most satisfactory parts of the book.

As one of the 12 volumes of the "Traité de Médecine et de Thérapeutique Chirurgical" it will doubtless fulfill its purpose, especially as it is prepared for a class of readers who apparently still hold the traditional view of orthopedic surgery.

The Surgery of the Heart and Lungs. A History and Résumé of Surgical Conditions Found Therein, and Experimental and Clinical Research in Man and Lower Animals, with Reference to Pneumonotomy, Pneumonectomy and Bronchotomy, and Cardiotomy and Cardiorrhaphy. By Benjamin Merrill Ricketts, Ph.B., M.D., Member of the American Medical Association, etc. New York: The Grafton Press, 1904.

Unlike many of the publications of the day the work before us represents something new and fresh in medical literature. The author, knowing that material concerning heart and lung surgery was scattered and poorly described, if not ignored, in the usual textbook, has set himself the task of collecting and sifting the published articles in many languages, and to this he has added his own personal experience in human surgery and an extensive series of experiments. These latter are especially valuable and praiseworthy, since they settle many points in technique which can be utilized when the need arises and will save much clinical experimentation. The first part of the volume treats of the heart, giving its anatomy, abnormalities, description of various injuries, inflammations, aneurysms, tumors, parasites, and deals quite extensively with the histories of peculiar conditions and, where surgery had dared to interfere, with the procedures employed and the results obtained. The author concludes the first part with his experiments on forty-five dogs, in which the heart, pericardium, and diaphragm were injured, and gives his deductions therefrom. The second part deals with pul-

monary conditions, foreign bodies, abscess, rupture, wounds, atelectasis, tumors, parasites, etc. All these are treated thoroughly where the histories allow and the writer succeeds in showing what brilliant results modern surgery has accomplished, notwithstanding the objections of Reclus and other conservative surgeons.

The bibliography is extremely rich; so rich, in fact, that the author disclaims reading it all, contenting himself with a thorough verification of his own text and citations and with a knowledge of the important contributions. Over eighty-seven plates add to the value of the work, which is one of which American literature may well be proud.

Normal Histology. By Edward K. Dunham, Ph.B., M.D., Professor of General Pathology, Bacteriology, and Hygiene in the University and Bellevue Hospital Medical College, New York. Third Edition (Revised and Enlarged). New York and Philadelphia: Lea Brothers & Company, 1904.

The writer has had large experience in teaching normal histology to medical students under conditions which require economy of time. He presents early in the course certain generalizations concerning the cell, and the mutual dependence of function and structure. He elaborates these ideas by dividing the activities of the body cells into four theoretical groups, as follows: The reproductive activities, leading to the production of new cells; the formative activities, through which the structural modifications resulting in the formation of different varieties of tissue were brought about; the nutritive activities, maintaining the integrity of the issues already formed; and the functional activities, through which the tissues serve the whole organism of which they are constituent parts. A valuable addition to the present volume is a section on histological technique, in which this subject is clearly treated. Complicated methods are not discussed. The book is well adapted to the use of both students and practitioners.

De la Escoliosis. Por el Doctor Saturnino García y Hurtado, Profesor de Ortopedia y Enfermedades de los Huesos, Musculos y Articulaciones del Instituto Rubio y de la Beneficiencia de Madrid. Madrid: Idamor Moreno, 1904.

This little 16mo volume, of about 100 pages, contains a well-written and altogether sensible monograph on lateral curvature of the spine by an orthopedist of large experience. A careful study of the mechanics of the normal spine is followed by chapters on the etiology of the deformity, its symptoms, and its treatment. The author is rather optimistic in his views regarding the benefit of treatment, for he holds that the deformity, if taken early, can be prevented, and that cases of moderate intensity may also be relieved by a persistent course of treatment extending to a period of from six to twelve months; even most advanced cases can be greatly benefited by well directed measures of correction. There are forty-eight half-tone illustrations showing the deformity in its various stages, various forms of apparatus and exercises designed to overcome the deflection of the spine, and the results of treatment. The little book contains a conscientious study of a difficult subject by a man of experience and judgment, and it is a valuable contribution to the literature of scoliosis.

The Purin Bodies of Foodstuffs, and the Rôle of Uric Acid in Health and Disease. By I. Walker Hall, M.D., Assistant Lecturer and Demonstrator of Pathology, the Owens College, etc. Second Edition (Revised). Philadelphia: P. Blakiston's Son & Company, 1904.

In the second edition of this work the results of recent researches have been included, the literature brought up to date, a new chapter on the action of drugs on purin excretion added, etc. The book is devoted to an account of the author's researches on the metabolism of those bodies, constructed on the nucleus C_5N_4 which E. Fischer styled the "purin bodies,"—including uric acid, xanthin, etc. The book is a most important contribution to the literature of the subject, but it is a pity that it was not written with reference to the needs of the reader unacquainted with this theme. Such readers should study the introductory chapter and then pass on to Chapters VII and VIII, on the Fate of the Purin Bodies of the Food, and the Rôle of Purin Bodies in Disease, respectively. They may then read the rest of the book with profit. Clinicians and laboratory workers will be especially interested in the description in the author's apparatus styled the "purinometer," for estimating the amount of purins in urine. We regret to note that the make-up of the book shows haste, and that there are a number of avoidable misprints.

A Treatise on Applied Anatomy. By Edw. H. Taylor, M.D. London: Charles Griffin & Company; Philadelphia: J. B. Lippincott Company, 1904.

It is almost universally admitted that in some respects there is a wide gap which separates the dissecting room from the surgical operating theater, and that if these two branches were brought into closer relation from the pedagogic standpoint, the subject of anatomy would possess greater attraction for the student and thus serve a more useful purpose. At present it is largely taught as an abstract science, and the bare facts without the leaven of application are difficult to remember. The recognition of these factors has resulted in the establishment of courses in applied anatomy in a number of medical schools and their value has been duly proved. It may be that in the course of time the accepted textbooks of anatomy will be relegated to the shelf as works of reference, and the student's guide, after he has assimilated the general principles of the subject, will be a book of the character here reviewed. The author frankly confesses that his book is mainly surgical and that its scope might be more correctly expressed by giving it the title: "Surgery from the Anatomical Standpoint." In the text the anatomy of each region is introduced by a concise account of its topography, developmental details being supplied where necessary, and subsequently the more important lessons, medical, surgical, and pathological, which are derived from it, are presented for consideration. The book is written in good, concise English, and includes the anatomy of the entire body in a sufficiently complete form for all the needs of student or practitioner. The illustrations are numerous and excellent, and largely taken from special dissections. As there is an urgent need for works of this type, the book will undoubtedly meet with a favorable reception.

A Practical Treatise on Genito-Urinary and Venereal Diseases and Syphilis. By Robert W. Taylor, A.M., M.D., Clinical Professor of Genito-urinary Diseases in the College of Physicians and Surgeons, New York. Third Edition (Revised and Enlarged). Philadelphia and New York: Lea Brothers & Company, 1904.

This new edition of Dr. Taylor's well-known work offers no novelty of style or arrangement, the plan of the previous edition being adhered to in all essential particulars. The changes which have been made consist in revision of the text and additions of new sections and illustrations in order to bring the book abreast of the times. This appears to be a resting period in genito-urinary work, real progress in that division of medical activity being for the moment in abeyance. Old theories are being proved and some new remedies are being tried, but of actual discovery or of any real advance there is practically none. One may, therefore, possess himself of this new edition, which is thoroughly up to the present date, with the confident assurance that it will be a long time before he will have to discard it for something more modern—unless the G.-U. men throughout the world "get busy." At present if it were not for the prostate (and that has been pretty well milked), genito-urinary societies would have to adjourn for want of material and men, as the national association actually did last summer in St. Louis.

The Theory and Practice of Infant Feeding. With Notes on Development. By Henry Dwight Chapin, A.M., M.D., Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital; Attending Physician to the Post-Graduate, Willard Parker, and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital. Second Edition (Revised). With Numerous Illustrations. New York: William Wood & Company, 1904.

The second edition of this admirable book, appearing in less than two years after the first edition was issued, is only additional proof of the well-known excellence of the work. The text is divided into four parts: Underlying Principles of Nutrition; Raw Food Materials; Practical Feeding; Growth and Development of Infants. As the author tells us in the preface, when the first edition of this book was printed, many authorities thought that the correct basis of scientific artificial infant feeding was an adjustment of the quantitative differences of cow's milk and breast milk, as well as the change of the acid reaction of cow's milk to alkaline reaction by the addition of sodium bicarbonate or lime water. The basis, in other words, was supposed to be purely chemical. But the author never agreed with the view that the suitability of infants' food depends alone upon its chemical composition. In the last two years great advance has been made in the knowledge of the chemical composition of breast and cow's milk, and many of their supposed differences have been found not to exist—for example, that of reaction. New discoveries have made much clearer both the physiology of milk and the true principles of artificial feeding. The author emphasizes the fact that the milk of each type of animal must be studied from the standpoint of its special adaptability to the particular digestive tract for which nature intended it. He also treats at some length the fundamental question of how to get clean, fresh cow's milk.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Annual Meeting, Held in St. Louis, September 13, 14, and 15, 1904.

(Continued from page 555.)

Gunshot Wound of the Abdomen.—Dr. JOHN S. DAVIS, of Birmingham, Ala., reported a case of gunshot wound of the abdomen, with eighteen perforations, in which he resorted to intestinal resection of five feet, seven inches, with use of metal button, followed by recovery of the patient. The ball in traversing the abdomen made eighteen perforations of the gut, and two cuts in the intestine that went to the mucous membrane. Sixteen of the perforations and the two seromuscular wounds were in the small intestine, and two perforations in the transverse colon. The bullets cut two mesenteric arteries, which caused a large amount of blood to collect in the abdomen. The patient, a woman twenty-three years old, was shot at four-thirty o'clock in the afternoon, Feb. 2, 1904, and was brought a distance of eighty miles on a freight train to Birmingham, by her physician, Dr. W. O. Watson, and carried to Hillman Hospital. At nine o'clock the writer saw the patient and had her prepared for operation. The temperature at this time was 102°, and pulse 130. She probably had fever at the time she was shot. A seven-inch incision was made in the median line, a large quantity of blood turned out, and the bleeding vessels controlled by hemostatic forceps. The two perforations in the transverse colon were so near the mesenteric border that he stripped up the mesenteric serosa and turned the mesenteric border in as though the two openings, one on each side, had been one large opening, including mesenteric border, and closed with interrupted silk sutures. He then brought the mesenteric folds back and sutured over the wound. Four perforations and two seromuscular cuts in the small intestine were turned in and closed with small loop silk sutures. Two perforations were situated so close together that they had to be closed by flexing, pouching, or looping the mesenteric border, the bowel being bent on its convexity so the two wounds could be closed as one large wound by interrupted longitudinal loop sutures,—in the avis of the bowel. There were two other perforations that could have been closed by suture, but the openings were between two mesenteric perforations on one side, and eight on the other, and he thought it better to lose one more foot of intestine than to do two resections. He resected that part of the intestine containing the ten mesenteric perforations (sixty-seven inches), including the two large perforations in the convexity of the ileum and closed with the third sized metal button. The resected bowel and its mesentery were removed, the vessels ligated, and the gap in the mesentery closed with interrupted silk sutures. The abdomen was flushed with hot decinormal salt solution; plain gauze drainage was used, and the abdomen closed with through and through silkworm gut sutures. The operation lasted one hour and a half. Drainage was removed on the second day. Patient passed the button on the twenty-first day, and left the hospital March 1, 1904. A week later she was doing housework, and was now perfectly well. Dr. Davis exhibited the metal button, which was made in four sizes, like the Murphy button, with the exception that it had no spring. In his opinion, the spring served no good purpose, was an additional expense, and made the button more difficult to apply. He also showed a metal horseshoe button which he had made to take the place of his catgut horseshoe plates, which he had been in the habit of using to close large wounds on the convexity of the bowel without destroying the mesenteric border by resection.

Some Clinical Reasons for Advising Early Operations in Cases of Fibroid Tumor of the Uterus.—Dr. RUFUS B. HALL, of Cincinnati, O., discussed this subject under three heads: (1) In which cases should we advise no operation? (2) In which cases should we advise late operation? (3) In which cases should we advise early operation?

1. If a patient between 35 and 38 years of age, suffering from a fibroid tumor of the uterus, the tumor and uterus combined making a mass not larger than a cocoanut, had no symptoms other than profuse metrorrhagia, the whole period not extending over five or six days, and she was free from pain except at her menstrual periods, it would be wise and judicious not to interfere surgically. But this patient, during her entire menstrual life, should be considered an invalid by her physician and should report to him at once if her symptoms became aggravated.

2. If she suffered pain in one or both iliac regions at other times than at her menstrual periods, the cause of the pain should be discovered at once and corrected. On the contrary, if her menstrual period was prolonged to ten or twelve days, the loss of blood amounting almost to a hemorrhage, and this hemorrhage could not be controlled or mitigated by the usual internal medication, and rest during the period, the advisability of an operation should be considered.

3. Prolonged and severe uterine hemorrhage had not been considered a sufficient reason for advising an operation. A patient suffering from a tumor as large or larger than a cocoanut, who had profuse bleeding at each menstrual period, the period being prolonged for eight, ten, or fifteen days, as it frequently was, was in considerable danger. It was the author's experience that a large majority of those patients in whom the hemorrhage could not be controlled by medicinal remedies in two weeks came to operation sooner or later. They could frequently stand off the operation two or three weeks, or in some instances longer, but the anæmia was profound, and if some complication arose in the tumor, ovaries, or tubes, making an immediate operation necessary, they were in the worst possible condition for it. The chances for a successful operation were greatly diminished. Therefore, when the hemorrhage could not be controlled within a few months, these patients should be advised to have the operation done before the anæmia was pronounced. These symptoms, however, were not of so much importance as others, but if permitted to continue for many months they caused a profound anæmia and lowered vitality, and a high mortality followed the operation.

He regarded hæmatoma complicating these tumors as the gravest complication the surgeon had to deal with in the management of the late cases. His records showed that only one patient in seven operated upon for fibroid tumors, when pus tubes were present, developed peritonitis after the operation; while five in every six of those operated upon in which hæmatoma of the ovary existed suffered from peritonitis following the operation for the removal of the tumor.

Shall We Remove all Fibromata of the Uterus on Diagnosis?—Dr. THOMAS B. EASTMAN, of Indianapolis, Ind., read a paper with this title. After quoting freely numerous writers on the subject of the removal of the fibroid tumors, the author stated that in the 117 cases upon which he had operated for fibroid tumor of the uterus, complications which bade fair to result eventually in death were encountered in 43 cases. Hydrosalpinx, either unilateral or bilateral, five times; suppurating dermoid cyst, three times; sarcoma, once; parovarian cyst, once; necrosis of tumor, eight times; cystic degeneration of ovaries, three times; ovarian cyst, four times; intraligamentous development of fibroid, three times; pyosalpinx or salpingitis, seven times; hæmatosalpinx, once; cystic degeneration of the tumor, once; myxomatous degeneration, three times; adenocarcinoma of body of uterus, twice. Among the more prominent complications, appendicitis was encountered once. In addition to the complications inherent in the uterus and its adnexa proper, there were those arising from the pressure of the

mass upon the bladder, rectum, and ureters, and the persistent anæmia resulting from prolonged hemorrhages.

In the speaker's 43 complicated cases, as well as in those of the other writers on this subject, it was a significant fact that those complications which were inherent in the tumor and which presaged the most certainly fatal results, were those of such character as to preclude a positive knowledge or ofttimes even a suspicion of their existence prior to operation or, indeed, to microscopical examination. This, then, was the arraignment of the uterine fibromyoma, and in the mind of the author justified its removal in all cases, except in so few as scarcely to merit attention. The results obtained by various operators warranted one in classing the removal of a fibroma among the safe operations, the mortality being in the hands of skilled men scarcely more than five per cent., a mortality certainly much less than would result from the policy of procrastination, which advocated delay until the forces of death plus those of the operation outweighed those of surgical interference. There was nothing so innocent as an innocent fibroid, and nothing so treacherous.

Removal of the Skeleton of an Ectopic Foetus, Ulcerating Into the Bladder, by Vaginal Cystotomy.—Dr. William D. Haggard, of Nashville, reported the case of a white woman, aged 31, the mother of two children, who presumed herself to be normally pregnant and expected to be confined August 30, 1900. There was a continuous flow from the uterus for the first three months, and she had pain in the bladder and straining on micturition from the beginning of conception; but there was no history of rupture of the ectopic gestation. One June 20, at six and a half months, while lying down, she felt motion for the last time. Previously it had been unusually vigorous, more so than with her two other children. She was confined to her bed for three or four weeks with pain. She had more or less pain for about a year and she was a semi-invalid from weakness, pain, and tenderness in the lower abdomen. The enlargement of the abdomen had gradually, but appreciably, diminished. At the end of a year pus first made its appearance in the urine, and the first day after getting up, a bone, which was a fetal vertebra, made its exit through the urethra. During the second year she had been able to attend to all household duties, but occasionally would have several days of unusual bladder irritation, and pass a bone through the urethra. In the last four months she had passed all the long bones. Sometimes one would catch in the urethra. She would get hold of the free end and gradually pull it out. Commonly several days of comparative comfort would elapse before another one would set up irritation, and finally escape. In this way she passed eighty-five bones. Six weeks before admission to the infirmary she felt the discomfort of another bone, and had not been free from it since, nor had any bone passed. She had been in bed two weeks with pain in the lower abdomen, which was very intense on motion. Upon examination the bladder was exquisitely tender, crepitated upon pressure. The bones were covered with phosphatic deposit. She described a small lump to the right of the median line and low down, the remains of the once six and a half months' enlargement, but this could not be made out on account of tenderness. The urine was loaded with pus and phosphates, and exceedingly offensive. Curiously enough, the woman did not void it oftener than every six or eight hours. Micturition was very painful and after the urine was voided free pus was often expressed. Under ether, October 31, 1902, the index finger was made to enter the urethra without much effort, and detected numerous bones, and, communicating with the bladder, an opening into a lesser chamber on its right upper surface. There was a mass on the right to be made out bimanually about as big as a small orange, and communicated with the bladder much as a bow window with partially drawn curtains did with a room. The uterus was retroverted and not much enlarged. The bones were much too large to be removed through the urethra, and an incision was made into the vesicovaginal septum. The finger in the bladder through the uretha located the bone, and it was withdrawn with a forceps introduced through the incision. In this way fifty-two bones were removed. Some were embedded in granulation tissue in the remains of the ectopic sac, and were with difficulty removed. The sac and bladder were freely irrigated, and an artificial vesicovaginal fistula established for drainage, after Emmet's method of sewing the vaginal mucosa to that of the bladder by silver wire sutures. The operation, while tedious, was not attended with shock. The bladder was irrigated twice daily afterwards with boric acid solution, and the urine soon became normal. At the end of six weeks the artificial vesicovaginal fistula was closed successfully by silver wire sutures. A cystoscopic examination with the Bransford Lewis ureter-cystoscope revealed a healthy mucosa, and at the site of the former communication only a slight reddish depression was seen. The ureteral catheter failed to disclose any depth to this aperture, and the patient was discharged eight weeks after the operation, and had remained well since.

President's Address.—Dr. Walter B. Dorsett, of St. Louis, Mo., President of the Association, stated that in casting about for a subject upon which to address the Fellows, he had selected for consideration the various operations for the relief of retrodeviation of the uterus. He spoke of the excellent operative work which had been accomplished within the past few years, so that what he had to say was more of a résumé of what had been done surgically. He discussed the methods of operation, saying that the different plans of accomplishing the reposition of the uterus might be classified according to the route selected by the advocates of each. They might be divided into extraperitoneal, vaginal and intraabdominal. After considering and discussing exhaustively the different methods in vogue and indulging in some criticism of them, he stated that some of the methods did not merit the prominence they had obtained in the estimation of the profession at large, and for the reason that no one could arrive at a proper conclusion as to the best method of relieving the suffering woman without a careful study of the different methods. If one operation was in accord with the accepted idea of proper surgical technique, the other certainly was not. When one considered the great diversity of opinion as to which was right and which was not, without a proper appreciation of them all, one was certainly at a loss as to the choice of operations. In his opinion, one should not consider any operation that did not contemplate the possibility of a thorough inspection of the adnexa from above the pubic bone. He would discard the entire class of operations that contemplated vaginal incision, either anteriorly or posteriorly, on account of the greater liability of sepsis, as well as from the impossibility of anchorage to firm structures. While ventrosuspensions and ventrofixations had been condemned as unjustifiable, he took it that it was because only the fixation or suspension that was accomplished by anteverting the uterus and stitching the fundus, or, perchance, the posterior uterine wall, to the abdominal wall had been considered. It was reasonable to assume that this unnatural suspension or fixation was a causative factor in the production of lengthened adhesion bands for the entanglement of bowel as well as a barrier to the proper development of the pregnant uterus. If, however, a lower segment of the anterior uterine wall was attached lower down on the abdominal wall, and omentum was allowed to drop to or behind the uterine fundus, the bugbears of necessary cesarean sections in labor cases and entangled bowel would be less feared. His own work in obstetrics and with this operation justified him in this statement.

Gunshot Wound of the Hip Joint.—Dr. L. H. Laidley, of St. Louis, Mo., reported a case of gunshot wound of the hip-joint. The patient, aged eighteen, a visitor and looker-on, of remarkably vigorous constitution and unexceptionable

health, was shot in a brawl on "The Pike" at the Exposition on the 18th of June. He was admitted to the Emergency Hospital, and within one hour an abdominal section was made. Upon examination it was found that the ball had passed through the abdominal wall near McBurney's point, passing inward and slightly downward. On examining the viscera it was found that the ball had penetrated the cæcum, making two openings, one in front and behind, and passed down into the soft parts in the pelvis. These were closed up by Lembert sutures, the abdomen cleansed of large quantities of blood and escaping contents of the bowel, and the abdomen closed with through and through sutures. The patient left the table within an hour under very favorable circumstances, the pulse being 72, temperature normal. The next morning he complained of great pain in the hip joint and was unable to move that limb. For ten days his condition was favorable, when he gave evidence of disturbance, especially about the joint. Chills and fever and increased pain suggested an examination with the *x*-ray, which would have been used earlier were it not for the fact that they had not been provided with such an appliance up to that time. On July 11, after the bullet was removed, an incision was made over the joint, disclosing the presence of pus outside of the joint, which was opened, showing that all of the head of the bone within the capsule was entirely destroyed and fractured; likewise the acetabulum was fractured and necrosed. Following up the course of the cavity made by the bullet, the missile was removed, which was lodged in the upper and outer margin of the cavity of the socket. The necrosed portions of this bone were chiseled out, and with a sharp curette were entirely cleansed, likewise the dead portion of the head of the femur was removed, the cavity packed with gauze and thoroughly drained. He afterwards showed evidences of sepsis, which prompted the author on July 22 to reopen the wound, washing out the cavity and introducing further drains. These were continually used up to the present time. About three weeks ago the patient manifested evidence of acute nephritis. Upon examination it was found that he had a large quantity of albumin, with casts, which was evidently due to toxæmia, as found in scarlet fever. Since that time, by repeated cleansing of the cavity and thorough drainage, these evidences were disappearing, leaving the patient in a fair condition for recovery. The subsequent treatment would be to free the cavity and its surrounding structures of all suppuration, and by this means the author hoped to restore his patient to his normal health, probably leaving him with a shortening of the limb, and perchance a degree of ankylosis. The patient was exhibited.

Strangulated Umbilical Hernia.—Dr. John Young Brown, of St. Louis, Mo., reported an interesting case of complicated strangulated umbilical hernia, and presented the patient.

Sterility Due to Retrodeviation of the Uterus and Its Treatment.—Dr. Herman E. Hayd, of Buffalo, N. Y., read a paper on this subject, in which he reported twelve pregnancies following the simple Alexander operation. Among other things, he stated that posterior displacements of the uterus were a very frequent cause of sterility. Pregnancy had frequently followed when such a uterus was placed in position, either by pessary or operative measures. He made an eloquent plea for the simple Alexander operation for a large class of suffering women who had simple, uncomplicated retroposed uteri. In reporting the twelve cases in which pregnancy followed the simple Alexander operation it was pointed out that the ligaments had stood the test of pregnancy and parturition. The author urged that the simple Alexander operation should be always employed for this special class of sufferers, in whom a pessary was not worn with comfort or willingly tolerated.

Circumscribed Infection of the Placenta and Excessive Vomiting.—Dr. Albert Goldspohn, of Chicago, reported this case. There was a first pregnancy of three or four months, with severe nausea, and much vomiting almost from the beginning, with the gradual additional development of fever, and finally also severe chills and a scanty, foul discharge. There was no alteration in the shape and consistency of the cervix or of the body of the pregnant uterus. The patient had a rapid pulse, and irregular, high temperature and chills. The uterus was emptied. The membranes and ovum were intact. The edge of the placenta bore a circumscribed area of broken-down gelatinous tissue, with a very offensive odor.

Conservation of the Natural Resistanee of the Patient in Surgical Work.—Dr. Robert T. Morris, of New York, in discussing this subject, said that the late Lawson Tait was the first great exponent for conservation of the natural resisting force of the patient. Tait operated very quickly. He did as little as possible. He avoided handling viscera; he avoided disturbing the patient's mind with details of what he was about to do. He treated the most difficult cases lightly, and patients looked at it in the same light. The repair of surgical injury depended primarily, secondarily, and finally upon a proper hyperleucocytosis. The author used this term in a generic way to avoid elaboration of detail in statement. This was a manufacturing process carried on under the control and guidance of the sympathetic ganglia. The more the surgeon shocked a patient the more he lessened the production of the leucocytes. The common ways for lessening the natural resistance of the patient were prolonged anæsthesia, unnecessary amount of anæsthetic. All surgeons had seen patients who had been literally drenched with ether; they had seen patients carried to the danger line with chloroform. On the other hand, surgeons had watched the beautiful work of men who were expert in giving anæsthetics, who began with nitrous oxide and a little oxygen, then changing to ether, who did it skilfully, quickly, nicely, and avoided shock, which took away one element of resistance from the patient. Quick work was a point in which Tait excelled. Expeditious work conserved the natural resistance of the patient. Undoubtedly the resistance of patients was lessened in abdominal surgery by gauze packing. He said that if ten healthy policemen were taken from the street and a yard of gauze was introduced into the peritoneal cavity, these policemen the next day would not be in good condition. This being so, how could one expect a patient with septic appendicitis to be in good condition if a yard of gauze was packed into his abdomen. If one drained quickly, got out of the abdomen quickly, disturbed the bowels as little as possible, made short incisions—in other words, leaving the patient alone as nearly as possible, he would make such a wonderful recovery that one might be accused of taking out a normal appendix. The tendency was to do too much. If a surgeon pricked his finger in operating on a septic case, the surgeon died, while the patient recovered. Why was this? The patient was loaded with bacteria and toxins. The patient had called out all his resistance factors; his hyperleucocytosis was under way ready to meet infection and bacteria. The surgeon had not called out his resistance factors, hence the bacteria proliferated rapidly and gained ascendancy. Was it necessary for the surgeon to get all of the septic culture media out of the patient's abdomen? No. All he needed to do was to turn the scale; there was a conflict between the bacteria and the leucocytes in that patient's case; the bacteria were winning; the leucocytes were losing. What did the surgeon do? By taking out most of the toxins and bacteria quickly he turned the scale, turned the balance in favor of the leucocytes, and they went on and won. He took unfair advantage of them, but if he had labored conscientiously, in accordance with textbooks and the best authorities, he would have put the patient out of commission.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. H. W. Longyear, of Detroit, Mich.; *Vice-Presidents*, Dr. D. Tod Gilliam, of Columbus, O., and Dr. John Young Brown, of St. Louis, Mo.; *Secre-*

tary, Dr. William Warren Potter, of Buffalo, N. Y., re-elected; *Treasurer,* Dr. X. O. Werder, of Pittsburg, Pa., re-elected; *Councilors,* Dr. James F. W. Ross, of Toronto, Ont., and Dr. Walter B. Dorsett, of St. Louis, Mo.

After the introduction and adoption of resolutions of thanks the Association adjourned, to meet in New York city in 1905, the time to be fixed by the Executive Council.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held September 26, 1904.

WENDELL C. PHILLIPS, M.D., PRESIDENT.

Nominations.—Nominations of officers and censors for the ensuing year and of one hundred and seventy-five delegates to the Medical Society of the State of New York, to serve three years, were made.

The Work of the Summer Corps of the Department of Health.—Dr. JOHN J. CRONIN, Assistant Chief Medical Inspector, reviewed the work of this department since its incipiency, in 1876, when fifty Sanitary Inspectors were appointed. At the end of five weeks their services were dispensed with. Soon after this work was taken up, and has been a regular feature of the Department ever since. In 1893 Dr. Hermann M. Biggs conceived the idea that more good would be attained by visitations to parents of children and instructing them in regard to any vicious habits of feeding, etc. Pamphlets were printed in several languages for distribution for mother's instruction, giving words of caution regarding gastrointestinal diseases. Soon house to house visitation was taken up and advice given, especially regarding the care of babies when symptoms of summer complaint appeared. Where the sickness was severe enough to warrant it, a trained nurse was sent. If the sick child had been fed on store milk, that store was visited, and if found to be unfit for use, it was ordered to be dumped at once. If it was not too bad, the keeper was simply warned. Out of 900 stores visited, there were found 550 cases of violation; in two cases the temperature of the milk was found to be 84° F. Each year has shown improvement over previous years. To-day, when the Inspector visits the baby, he continues to see it; treatment is at once established, and, if necessary, a nurse is at once sent. The two factors which give the high mortality were (1) hot weather and (2) ignorance in caring for the children. The first factor cannot be changed, but the second factor can be gotten rid of to a great extent by education of mothers and distribution of circulars of information. They contend with the foreign population, because the mode of living here is opposite to the open-air life on the continent. Orders are given that all milk shall at once be stopped when summer illness of babies appear; but the Hebrews and Italians will not stop the milk giving. Bathing and sponging are taught the mothers, and has proven of great service. On hot and humid days they are told to bathe the babies with salt water. The deleterious effects of heat are best combatted by ocean trips, by visiting the piers and parks. The paved streets throw out heat during the night, making it difficult for the child to sleep; this could be obviated to a certain extent by flushing the streets after sundown. It was noted that one-third of the deaths occurred among children under two years old, who were fed on condensed milk and prepared cereals during the month of August. He felt justified in stating the heat *per se* was an important factor in causing the high mortality among children during the summer months. The report of the Inspectors during the past summer show 215,997 families visited, and history cards numbered 35,187, all of children under one year of age.

Precautions Used by the New York City Department of Health to Prevent the Spread of Contagious Diseases in the Schools of the City.—Dr. THOMAS DARLINGTON, Commissioner of Health of New York City, stated that the medical supervision of schools was undertaken in 1897. At that time it was found that children attended schools when the subject of mild attacks of measles, of scarlet fever, and sometimes even when they were desquamating, and not under medical care. In many the Klebs-Löeffler bacilli were found in throats. As a result of such findings money was appropriated and 150 Inspectors appointed for Manhattan and the Bronx in March, 1897. When a child was found to be suffering from measles or scarlet fever, he was at once sent home and the District Inspector notified; the latter would then exclude all children from the school until the termination of the case and the disinfection of the property. The detection of these diseases then depended largely upon the school teachers; once a week each child was examined. During the school year 1901-02 260,182 children attended, and there were 9,703 exclusions. In September, 1902, the routine inspection of schools was begun by classes; the children passed by the Inspector, pulled down their own eyelips, etc., the Inspector never touching a child. The Inspectors' reports are duplicated, one being sent to the Health Department, and the other kept on file at the school. The Inspectors found that many contagious diseases were not reported; during six months they found 561 cases of measles, 107 cases of German measles, 70 cases of scarlet fever, etc., that were not reported. A very large number of cases of pediculosis capitis were turned from school. Writing and drawing utensils were properly cared for. The public libraries received daily lists of homes where contagious diseases existed. Recently eight trained nurses were assigned to the care of children suffering from skin and contagious eye diseases. Tables for 1903 showed that there had been cared for 156,186 cases of pediculosis, 106,257 cases of eye diseases, 3,307 cases of eczema, 3,498 cases of ringworm, and 335 cases of scabies; the number of treatments numbered 235,793, and over 24,282 pupils had been visited. When five oculists were appointed it was found that 17 per cent. of the children were affected with trachoma. Later the Inspectors were sent for instruction in eye diseases at the New York Eye and Ear Infirmary, and they assumed the care of these sufferers. The number of trachoma cases was very great; 4,337 cases were operated upon; those not operated upon numbered 11,599; these cases were the hospital ones.

Disinfection, as Practised by the Department of Health of New York City.—Dr. ROBERT J. WILSON, Assistant Bacteriologist Department of Health, said there were two paths to actual disinfection, the Medical Inspector, who described what was to be done, and the Disinfector, who carries out the orders. It is the duty of the Inspector to go to the house, look over the rooms carefully, note how many cubic feet of air space there is, takes note of the number of doors and windows, and gains all the information necessary for the Disinfector to do his work. A card is given the Disinfector containing the desired information. The rooms are made as gas-tight as possible. During the past two or three years attempts have been made at bacteriological control by placing in the room to be disinfected living bacilli pyocyani on threads. On the day following this was sent in for growth; if the cultures were positive, then the disinfection was well done. For proper disinfection there were three essentials, as follows: (1) One must know the size of the room; (2) one must know how much gas it takes to fill the space to the extent of killing the germs; (3) one must know how long a time is necessary to destroy the organisms. Sulphur dioxide and formaldehyde were the only two disinfectants allowed the Board of Health. In different parts of Greater New York were disinfectant stations; the home disinfection gave only superficial destruction, and, at these stations, germs were destroyed which occupied the deeper parts of the fabrics. At these stations heat was employed at 225° F. for one or two hours.

Dr. WILLIAM HALLOCK PARK referred to the advance that had taken place since he entered the Department of Health, ten years ago.

Dr. CHARLES S. BENEDICT said that in the olden times sulphate of iron in paper bags, just enough for one day's disinfection, was given in each case of scarlet fever, and they were told to saturate thoroughly all the linen used.

He referred to the practical results of proper disinfection, and stated that in the epidemic of smallpox six or eight years ago, when there were cases in 72 different tenement houses, in only four instances were there secondary cases.

Dr. Frank Van Fleet commended the work that the Board of Health was doing.

Dr. John J. Cronin said that the Health Board had two oculists who did nothing but examine eyes of children. They did much good in noting any errors of refraction, as well as diagnosing trachoma, etc.

Dr. Thomas Darlington referred to the cordial relationship that existed between the Health Board and physicians. At railway stations they had condemned about twelve tons daily of fruits, etc., and in one day they had condemned forty carloads of soft stuff, such as fruits and vegetables. Even more work could be accomplished by the Health Board if they had more money and more Inspectors.

The Specific Treatment of Typhoid Fever.—Dr. J. M. Hackett, of Champlain, N. Y., read this paper (which will be published later).

Dr. Egbert Le Fevre said that he had had some experience with the purely mercurial treatment of typhoid fever, and he had seen a number of cases in which this was the routine treatment in certain parts of New York State. The mercurials had been administered until the constitutional effects had been obtained, and opiates were also given to control the cathartic effects of the mercurial. As a result, he had noted that the temperatures were reduced, but the mortality was higher than under the present plan of treatment. He believed that any plan of treatment would offer results, which varied, according to the epidemics; in the late epidemics the disease ran a shorter course as a rule. He had endeavored to find if he could make the intestinal canal antiseptic, and he failed absolutely. He doubted if there was any agent which would place the blood in a condition to destroy the Eberth bacillus. In the light of his own experience he said he was unwilling to adopt the method advocated exclusively as specific treatment for typhoid fever.

Chicago Medical Society

At a regular meeting, held June 1, Dr. Daniel H. Williams reported and exhibited three cases of penetrating wounds of the thorax, perforating the diaphragm and involving the abdominal viscera.

Dr. Julius Grinker read a paper on "Tuberculosis of the Nervous System," in which he said that tuberculosis of the nervous system was almost always secondary to tuberculous disease in some other organ. Of all tumors of the brain, tuberculous tumors constituted the great majority, and occurred with greatest frequency in childhood. Their place of predilection was the posterior fossa. The symptoms were the same as those of other brain tumors. As differential points might be given the tendency of tuberculous tumors to locate in the posterior fossa, to remain latent for long periods of time, to appear multiple, to have remissions in the symptoms. A localized meningitis could not be differentiated from a small tumor. Tuberculous leptomeningitis affected principally children from two to twelve years of age. The pathological changes took place mostly at the base of the brain, and symptoms of cranial nerve involvement stood out prominently. There were general symptoms due to brain pressure and focal symptoms due to localized implication of nerve tissue. Among the general symptoms were headache, vertigo, vomiting, slow pulse, disturbance of the respiratory rhythm, jactitation, convulsions, hyperæsthesia, delirium, coma, involuntary sphincter action, and possibly spasticity of the muscles, trismus, grinding of the teeth, retraction of the neck. These symptoms might be due to increased pressure in the brain. The focal symptoms might be caused by the accumulation of tubercles in certain cortical areas, or by direct involvement of the cranial nerves. Among these symptoms might be mentioned cranial nerve paralysis, especially of the third (strabismus, pupillary difference, myosis, or mydriasis), hemiplegia, aphasia. Typical cases were easily diagnosed. Atypical forms were most puzzling at times. The cerebrospinal fluid obtained by lumbar puncture must be examined chemically, microscopically, and bacteriologically. The technique was simple and could be found in any textbook. A blood examination would clear up many a doubtful case.

Tuberculous spinal meningitis without cerebral meningitis was extremely rare. The symptoms did not differ from other forms of spinal meningitis. Multiple neuritis and myositis of a most aggravated type occasionally occurred among the tuberculous.

Normally, the state of feeling was a correct index of the state of one's physical condition. In tuberculous patients this was often reversed. Their disease might be well advanced, and yet they laid plans for the future and showed a general hopefulness quite in contrast with their physique. Various neuroses and psychoses were met with in tuberculosis, and they seemed to stand in some close relation to that disease. The prognosis was unqualifiedly bad, and treatment was of no avail. Something might be expected from prophylaxis.

Dr. Aria Louis Derdiger read a paper on "Nervous Diseases and Eye-Strain." After comparisons of the family history and physical conditions in several hundred cases of neuroses, nearly all of whom had previously been under treatment, the writer formulated the following propositions, which were chiefly in accord with the teachings of Dr. Stevens and other investigators in this line of work: "(1) Hereditary neuroses, such as chorea, migraine, neurasthenia, epilepsy, and insanity, are not transmitted from parent to child directly. (2) Such neuroses are the manifestations of transmitted physical peculiarities, which make certain functions difficult to perform. (3) The hereditary physical defects which aid to develop neurosis, anomalous conditions of the eyes are among the most frequent etiologic factors, and prolific sources of nervous disturbances playing an important part in constituting a neuropathic tendency. (4) In all of the writer's cases no medication or other treatment had been used, aside from the atropin, prisms, correcting glasses and gymnastic exercises of the eye muscles. (5) By carefully correcting errors of refraction and existing muscular anomalies by prescribing the wearing of prisms and regulated muscular exercises, these exercises being continued for months, the writer has been able by persistent application of the wax taper and prism method to develop the weak muscles, overcome the eye strain, and practically relieve the functional nervous diseases, as well as the asthenopia, without operation."

Orleans Parish Medical Society.

At the regular semi-monthly meeting, held July 23, 1904, Dr. Samuel C. Landauer read a paper, entitled "Report of Cases of Malaria."

Dr. Joseph D. Weis read a paper, entitled "The Blood in Uncinariasis; Report of a Case." The examination of a blood smear for malaria revealed a eosinophilia of 70 per cent., by which attention was called to intestinal parasites. The blood showed: Hæmoglobin, 35 per cent.; reds, 4,800,000; whites, 20,000; polymorphonuclear neutrophiles, 20 per cent.; eosinophiles, 70 per cent. The last examination of the blood, three weeks after the last uncinaria were found in the fæces, showed: Hæmoglobin, 80 per cent.; reds, 5,800,000; whites, 8,000; polymorphonuclear neutrophiles, 68 per cent.; eosinophiles, 14 per cent. Ova of uncinaria were found upon examination of the fæces and 12 uncinaria in the first stool, after thymol had been given. From a study of statistics, the following practical points, the speaker said, could be drawn from an examination of the blood: Acute uncinariasis (six months to one year in duration) causes a leucocytosis, which leucocytosis is for the most part made up of eosinophile cells. The earlier the disease the higher the eosinophile count and the lecocytosis, and the later the disease the lower the leucocytosis and eosinophile count. Uncinariasis causes an anæmia varying in intensity with the number of parasites and with the duration of the disease. The greater the number of parasites and the longer

the duration of the disease the greater the anæmia, and vice versa. The anæmia does not simulate a pernicious anæmia, but rather a grave secondary anæmia, as evinced by the predominence of normoblasts, if, indeed, any nucleated red cells at all be present, microcytes, with slight poikilocytosis. Treatment of uncinariasis causes immediate gain in the number of red blood cells and an increase of hæmoglobin with a fall in the leucocytosis and percentage of eosinophile cells. The return of eosinophile cells to absolute normal occurs only after three or four months of cure. When a case of long duration shows, after specific treatment no reactionary rise in the eosinophile cells, nor increase in hæmoglobin and red cells, the prognosis is grave; it is in contradistinction good when such rise does appear. In cases of short duration the fall in the percentage of the eosinophile cells, with a rise in the red cells and the hæmoglobin, is of good prognostic import, and the absence of such a fall in the percentage of eosinophiles is grave. An excess of bloodplates was a constant feature of this case. The practical point is that a chloroanæmia, with or without elevation of temperature, associated with a constant eosinophilia of 6 per cent., and above, is enough to justify the giving of thymol when examination of the fæces is impractical or even negative.

Dr. Joseph Hume read a paper, entitled "Principles Underlying the Therapeutic Treatment of General Pyogenic Infections, with Especial Reference to Intravenous Injections of Nitrate of Silver Solution," in which cases were cited to show that such injections were of decided value, even in desperate cases. About 500 c.c. of a 1-10000 solution, repeated, if necessary, had been found to cause a temporary destruction of leucocytes, followed by a marked leucocytosis, with great improvement in all septic symptoms.

At the regular semi-monthly meeting of the Orleans Parish Medical Society, August 27, 1904, Dr. L. G. LeBeuf read "A Clinical Report on Eclampsia, with Treatment." The histories of five cases were given. The treatment preferred had been directed towards increasing elimination from bowels, kidneys, and skin, and at breaking the cycle of convulsive seizures by heroic doses of narcotics. Saline infusions, and enemata, pylocarpine, digitalin, nitroglycerin, morphine and chloroform were the medicinal agents found especially useful. Cardiac stimulants as indicated. The absolute individuality of each case was insisted upon.

Dr. D. L. Watson read a paper on "Acute Parenchymatous Nephritis in Pregnancy; Puerperal Convulsions; Report of Cases." The writer considered all puerperal eclampsia to be dependent upon diminished renal elimination. He believed also that prodromes could generally be noticed 36 to 48 hours before convulsions began. Headache, blindness, and epigastiric pain in a puerperal woman should always be taken as indications for beginning treatment. Large doses of morphine and pilocarpine, repeated once after five or six hours, if necessary, had proven most satisfactory in his hands. One-third to one-half grain of morphine, and one-twelfth to one-sixth grain of pilocarpine had been the doses used.

Dr. H. B. Gessner read a paper entitled "Nerve-Blocking to Prevent Amputation Shock; Illustrative Report of Thigh Amputation." The reader began by referring to a paper published on this subject by Dr. Howard Cushing in the *Annals of Surgery* for September, 1902, and quoting from that paper the principles in which nerve-blocking in amputations is based. He then reported two cases of thigh amputation in which absence of immediate shock was noticeable. In the second case an increased pulse rate (110 to 136) was observed after 24 hours, but stimulation was followed by improvement and recovery. The conclusion was drawn that the method, which required less than five minutes for its application, was well worth more extended trial.

Treatment of Appendicitis.—Pel does not share the opinion of Dieulafoy, who advises postponing the operation until the appendicitis has run its course. He attributes the large mortality of acute appendicitis in France (30 per cent.) to the frequent early operations. According to Pel, the operation should be delayed until the abscess is encapsulated, a period which is not always easily determined—usually in the second or third week of illness. All symptoms of infection, hectic fever, small pulse, leucocytosis, tumor in the iliac fossa, are evidences of abscess formation. This is the time for the incision, which, if possible, is to be conjoined with the removal of the appendix. If a general peritonitis develops as the result of perforation or extension of the inflammation, Pel advises postponing the incision until the peritonitis is localized in Douglas's sac or the liver.—*Weekblad van het Nederlandsch Tijdschrift voor Geneeskunde.*

Cerebro-Spinal Meningitis	.....	13
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	868	215

Campaign Against Tuberculosis in Germany.—The campaign against tuberculosis in Germany has hitherto consisted chiefly in the establishment of sanatoriums. A committee has recently been formed at Berlin for the purpose of devising measures for fighting consumption in towns and dwellings. It is proposed to enlist the active support of all medical practitioners in Berlin and its suburbs with a view to the formation of an organization for the notification of the disease and the care of patients suffering from it.—*British Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended September 30, 1904:

PROLAPSE OF THE OVARY. AN OPERATION FOR ITS CURE, WITH REPORT OF TWELVE CASES.

By CHARLES CLIFFORD BARROWS, M.D.,
NEW YORK.

When one takes into consideration the number of women suffering from the effects of prolapse of one or both ovaries, who present themselves to the gynecologist and seek relief from the distressing symptoms dependent upon this condition, one can but feel that too little attention has been given by writers on gynecology to measures calculated to bring about a cure of so serious an ailment. This statement may be easily demonstrated by reference to any of the text-books on this subject at the hands of the students of to-day. Some do not refer to the condition at all, except when complicating some other lesion, while few of them give more than passing notice, and with no definite plan of treatment, looking to a cure,—or with suggestions for operation which, in my experience at least, have proved wholly inadequate and unsatisfactory.

That prolapse of the ovary, to such a degree as to give rise to well-marked symptoms, is a common condition as proven conclusively to me by the observation of more than one hundred cases in two thousand operative gynecological cases coming into my hands during the past ten years. In speaking of prolapse of the ovary, I refer to that condition in which the ovary sinks backward, downward and inward, usually ultimately resting in Douglas's pouch. In this consideration of the subject it is not intended to deal with purulent deposits within the ovaries or Fallopian tubes. The object of the paper is to offer for your consideration and criticism an operation for the relief of conditions resulting from ovaries which have become prolapsed from causes which have not brought about suppurative processes in these organs, and particularly for ovaries prolapsed and non-adherent; though this does not preclude the consideration of adherent or enlarged or cystic prolapsed ovaries.

It has been commonly taught that the left ovary is more frequently prolapsed than the right, and various reasons have been offered in explanation of this belief: such as the absence of a valve in the ovarian vein on the left side, and the consequent hyperæmia of the ovary and predisposition to disease for this reason, or the dragging of the ovary downward by the passage of masses of fæces along the rectum.

In my experience, based upon the study of more than a hundred cases, the right ovary is more commonly prolapsed than its fellow. In about seventy per cent. of my cases the right ovary was lower than the left. It is not difficult to understand why this should be so. The right side of the pelvic cavity is practically vacant, with abundant opportunity for descent of the ovary, provided conditions in the gland, or its supports, favor this displacement, while the left pelvis is filled by the rectum, more or less distended with fæcal matter, and there is, consequently, less opportunity for displacement of the ovary downward and backward.

So far as the treatment goes, the question as to whether the right or left ovary, or both, be prolapsed, is of no consequence. The same procedure, looking to the relief of the condition, is applicable in all these cases. The simple increase in weight of the gland may be sufficient cause for prolapse of the ovary, and we quite commonly find this condition associated with enlarged cystic ovaries, where no other pathological condition is present. It may be displaced by pathological growths, or drawn down by posterior displacements of the uterus, or by adhesions resulting from pelvic inflammations. Any condition which increases the weight of the organ, by hyperæmia or inflammatory disturbances, or relaxes its supports, may give rise to prolapse of the ovary.

While this condition is quite commonly associated with retro-displacements of the uterus, it is also frequently found present in acquired anteflexion of the uterus, these conditions, in all probability, both being not uncommonly dependent upon the loss of tone of the tissues in subinvolution of these organs after pregnancy. And again, we find one or both ovaries prolapsed, in various degrees, where the uterus occupies an entirely normal position in the pelvis, and where no diseased condition of that organ or the ovary, other than its malposition, exists.

The one condition which is, in a vast majority of cases, responsible for the descent of the organ is relaxation of the supports of the uterus and ovaries, and when we consider with this those pathological changes which increase the weight of the ovary, we have practically comprised the etiology of the condition under discussion.

Relaxation of the supports of the uterus and ovaries is very commonly found in women who have borne children, and in whom involution has been unsatisfactory, the broad and round ligaments and vaginal roof being so relaxed as to permit the uterus and ovaries to sag toward the floor of the pelvis; but the condition is, by no means, infrequent in anæmic women, who are of poor fibre or physically depressed from other general causes.

Of the many causes which may increase the weight of the ovary, cystic degeneration is the one most frequently found where this organ is prolapsed.

Normal menstrual congestion, or any condition producing passive or inflammatory hyperæmia, acute or chronic interstitial inflammation, or puerperal subinvolution, or possibly early ovarian pregnancy, may add to the weight of the organ, and thus prove a potent factor in the causation of its descent in the pelvis. The question as to whether the enlargement of the ovary be the cause or the result of its displacement at once suggests itself.

Fig. 1.

It is a fact, based upon actual observation of very many cases, that it rarely occurs that a prolapsed ovary is found of a normal size; but whether the enlargement be primary or secondary has no bearing upon the point at issue in this paper, in which is offered you an operation for the relief of the condition as it exists, without regard to its causation.

In a large proportion of the cases of retrodisplacement of the uterus, there is prolapse of one or both ovaries, and at times it happens that the restoration of the uterus to its normal position by shortening the round ligaments, within or without the pelvis, will lift the ovaries within the pelvis and partially restore them to an improved, if not a normal, position. But I have found by actual experiment that this improvement of position of a prolapsed ovary but seldom follows the restoration to its normal position of a retrodisplaced uterus. And the reason is a very simple one. Practically, in every case of prolapsed ovary coming under my observation the ovarian ligament itself, and the mesovarian or ligament which suspends the ovary to the broad ligament, the suspensory ligament of the ovary, are relaxed and elongated, and the descent of the gland into Douglas's pouch is possible, even though the supports of the uterus be absolutely intact. A careful study of this condition has shown that the two folds of peritoneum which, with the enclosed vessels, form the mesovarium, is so elongated and relaxed that even when the other supports of the uterus are drawn up into an exaggerated position, the ovary drops at times well into Douglas's pouch. So that, as I have said, the prolapse of the organ depends practically on relaxation and elongation of the mesovarium. (See Fig. 1.) This will be more clearly brought out in the description of the operation which I offer for consideration in this paper.

Let me, in a brief way, present some of the more important symptoms and signs which lead us to the diagnosis of prolapse of the ovary. The symptoms are local and general, and their severity and importance depend, in a measure, on the amount of prolapse and the questions as to whether the ovary is acutely or chronically inflamed. There are certain symptoms which are almost sure to be brought to our consideration by every woman suffering from pelvic disorder of any kind, such as backache, dragging sensations in the groins and thighs, bearing down and weight in the pelvis, sacralgia and neuralgic pains in the hips and thighs. These symptoms almost always exist in women suffering from prolapsed ovaries, but they are not pathognomonic. But when we add to them difficult and painful defecation, numb, sickening pain on coition, greatly increased pain on walking and sitting and, at times, nauseating pain, when a sudden false step is made, or an unusual jar is given to the body, such pain as might be analagous to that brought about by a blow or pressure on the testicle, we may suspect the condition which we have under discussion. This sickening, nauseating pain may be easily produced in a healthy patient, whose ovaries are palpable by bimanual pressure on these organs. The degree of these symptoms depends, in a measure, on the position of the uterus. When the uterus is well forward in the pelvis, the symptoms are much less marked than when it is posteriorly displaced. (Fig. 2.) The constant pressure of a retroverted uterus on a prolapsed ovary lying in Douglas's pouch, unless relieved, requires but a short time to render the patient a helpless invalid. (Fig. 3.) This condition of affairs is, as we know, one of the commonest causes of early abortion, as I shall show in some of the cases that I report. Women suffering from an exaggeration of this condition walk and sit down or rise from a chair with such

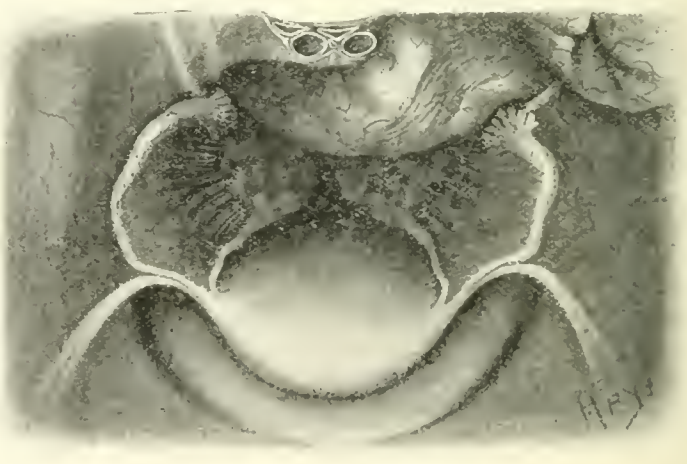

Fig. 2.

caution that I have at times been almost tempted to make a diagnosis without asking them a single question. The general symptoms are quite characteristic. The patient is usually thin, poorly nourished, anæmic, "run down," as she will express it, extremely nervous and irritable, possibly at times hysterical, especially as the menstrual period approaches. She suffers from frequent, sometimes almost constant, nausea, loss of appetite, impairment of the digestive functions, and constipation.

These conditions may become so exaggerated by long continued suffering as to unsettle the patient mentally, or bring about a condition of invalidism pitiable in the extreme. Perhaps it may be well to consider whether these symptoms may not be due to the condition, and not the position, of the ovary; whether, for instance, the cystic degeneration of the ovary may not give rise to all the distressing symptoms which we have just mentioned, without reference to where in the pelvis that ovary may be located. That the position of the ovary surely is of by far the greater importance in such cases seems clear, when we consider that we find ovaries normally situated which have undergone marked cystic degeneration without symptoms of any kind, and then again, we find prolapsed ovaries devoid of this pathological condition in patients presenting the whole train of symptoms which we have described above.

Digital examination reveals without difficulty the presence of the ovary in Douglas's pouch, the organ being at times so exquisitely sensitive as to make a satisfactory examination impossible without an anæsthetic.

So distressing are the conditions which are brought about by prolapse of the ovaries, so un-

Fig. 3.

satisfactory have I found all forms of palliative treatment in a large majority of cases, and so wholly inadequate have been the measures of relief in the hands of the surgeon, up to the present time, that I do not hesitate to offer for consideration the operation which I have devised, and taught to the students in the classes at Cornell, and which has proved so satisfactory in my own hands in the cases, the reports of which will follow.

Various measures have been suggested for the surgical relief of this condition, such as the shortening of the round ligaments within or without the pelvis, or this measure combined with the shortening of the infundibulo-pelvic ligament, or one or both of these procedures, together with the "stitching" of the ovary to the round ligament, or the suturing of the ovary to the face of the broad ligament. The more rational operation seems to me to be that suggested by Hirst, *i.e.* suspension of the infundibulo-pelvic ligament to the parietal peritoneum over the iliopsoas muscle above the pelvic brim and in front of the iliac vessels. I have had no experience with this operation, and it would seem to meet the indications where the prolapse of the ovary depended on the relaxation of the infundibulo-pelvic ligament without relaxation or elongation of the mesovarium. Such cases, in my experience, are, however, rare. Then, too, the sagging of an artificially suspended ovary in an abnormal position, we can readily understand, might easily give rise to distressing symptoms. Indeed, it requires but small practical experience to prove to any one how absolutely futile, in a majority of cases, these procedures are, since, as I have shown you in prolapse of the ovary the mesovarium or, as I may call it, the suspensory ligament of the ovary itself, is relaxed and elongated, and it matters not how much one shortens either the round ligament or the infundibulo-pelvic ligament, or both, if nothing further be done, the ovary will be scarcely changed in its position in Douglas's pouch. As to stitching the ovary to the round ligament, that is absolutely so unsurgical, since it must necessarily interfere seriously with the Fallopian tube—that organ lying between the two structures that are to be brought together—that it does not even deserve serious consideration.

Realizing the inadequacy of these procedures, and feeling quite sure that in the hands of many gynecological surgeons, these prolapsed ovaries, especially when they were inflamed or cystic, were sooner or later sacrificed, I have during the last few years attempted several plans of operation with the hope of maintaining these organs in a position where their functions would not be interfered with, and where they would not give rise to the distressing symptoms which we have considered.

I shall not recount in detail the various attempts at suturing the ovary to the broad ligament or the several other efforts which about two years ago led me up to the operation which I now propose. This work has been done along the same lines as those drawn by me in a paper read before the New York Obstetrical Society in 1893, on "Conservative Surgery of the Uterine Appendages," and has for its motive and purpose the preservation to the patient of those organs whose healthy functional activity have so much to do with the health and happiness of every woman. The cases which I shall report are, I believe, sufficient to show quite satisfactorily that prolapsed ovaries may be placed in such a position in the pelvis as not only to permanently relieve the patient of the distressing train of symptoms from which she has been suffering, but to permit these organs to carry on their functions relating to both ovulation and menstruation in a perfectly normal and healthy manner.

The abdominal cavity is opened under the usual aseptic precautions, the patient being then preferably placed in the Trendelenburg posture. It is not necessary to make an extensive incision,—two inches, at most, being ordinarily sufficient. The intestines are held back from the field of operation by three aseptic bolsters, such as are shown in the illustration, one being placed in the median line and one in each lateral fossa. (Fig. 4.) In work of this kind, I have found these bolsters in every way superior to gauze pads or rolls of gauze, as may be easily understood. When properly introduced, the pelvic cavity is completely shut off, the intestines being held back behind the wall formed by their adjustment. All adhesions about the tubes and ovaries are broken up and any cysts that may exist in the ovaries are punctured, the wall being removed if

the cyst have a definite cyst-wall. In this connection it is, perhaps, wise to say that it may be necessary to remove considerable portions of the ovary which have been destroyed by chronic cystic degeneration, the incision in the ovary being closed by interrupted sutures of fine catgut or silk. The round ligaments are then caught up and shortened, after the manner suggested by Wylie, two fine silk sutures being sufficient to accomplish this result.

Fig. 4

(Fig. 4.) In case the uterus is markedly anteflexed and the round ligaments not relaxed, this part of the procedure may be omitted. In this connection I will say, however, that in all the cases operated on by me I have found this step necessary. The next step of the operation consists in shortening the infundibulo-pelvic ligament after the same manner as that followed in shortening the round ligaments. The infundibulo-pelvic ligament is caught up by forceps and a reef of say one or two inches taken in it and secured by two or three sutures of fine silk. (Fig. 5.) Thus far, it will be seen that the operative procedure does not differ materially from that recommended by the text-books generally. And if we stop at this point to examine the anatomical conditions brought about by the operation, we will find that the state of the patient is worse than before the operation was begun. The ovary has not been lifted from Douglas's pouch because of the elongation and relaxation of its own ligaments, and in addition to this, by the shortening of the round ligament and the infundibulo-pelvic ligament, the layers of peritoneum between these two structures have been stretched tent-like above it, and the ovary is buried in Douglas's *cul de sac* and hidden from view by this roof which has been thus drawn over it. If we examine carefully this triangular fold of double peritoneum, we find that, surgically considered, it practically contains no other tissues except the two peritoneal membranes. It is thin and almost transparent, and contains no blood vessels of any consequence. In this double peritoneal fold, which is thus stretched between the round ligament and the top of the broad ligament, a small linear incision is made, say half an inch long, and the ovary, which lies beneath it, is brought through the opening and permitted to lie on the shelf thus provided for it. This, as you will readily see from the drawing, interferes in no way with the relations of the Fallopian tube to the ovary or of the blood supply to and from the ovary. In order to secure the ovary in its new situation, a suture is taken at either extremity of the gland, thus limiting the incision and securing the organ permanently in its new position. This procedure permits the ovary to rest comfortably on this top shelf of the pelvis, secure from any possible impact of the uterus, one of the causes of the intense suffering in prolapse of the ovary, and it does not in any way interfere with its functional activity or with its important relations to the Fallopian tube. The simplicity of the procedure, and the ease with which it may be carried out by any abdominal surgeon, should recommend it as a possible cure for a most distressing condition, which I do not hesitate to reiterate has, until now, usually resulted in the sacrifice of one or both ovaries.

In a paper read before the Society of the Alumni of Bellevue Hospital I have used the term "shelving the ovary" to describe this operation. This, however, is not an entirely satisfactory title in that it may convey the idea that the organ is put out of commission by being put on the shelf, whereas the operation was devised for the purpose of putting the organ in a position where it could do its work well, with ease and comfort to its owner.

In illustration I offer the following cases:*

Case I.—K. M., 22, married, by profession a ballet dancer, consulted me May 1, 1902. The patient was pale, apparently very anæmic, thin and poorly nourished, extremely nervous, and emotional. According to her statement she began to menstruate when she was thirteen years of age, and her menstruation had always been normal as to quantity and regularity, except when interfered with by pregnancy. She has been a dancer since childhood, and from the time she began to menstruate she has suffered from severe backache, pains in the pelvic region shooting down the thighs; these being greatly increased on exercise, and on more than one occasion she has fainted on the stage from sudden, intense, agonizing pain in the pelvis. Chronic constipation and painful and difficult defecation have been present, and dyspareunia has existed to a

Fig. 5.

*The cases operated on by me in Bellevue Hospital were in Prof. Polk's service, and it is through his courtesy I am permitted to report them.

marked degree. The patient has been three times pregnant, each time aborting about the third month.

On examination I found the uterus normal in size and position, with both ovaries enlarged and tender, prolapsed and resting in the bottom of Douglas's pouch. The abdomen having been opened, the condition as diagnosed was verified. Both ovaries being the site of extensive cystic degeneration, about one half of each organ was removed, the incision being closed with fine catgut sutures. The round ligaments were shortened just sufficiently to avoid any undue traction on the uterus, that organ being in its normal position. The reef in the ligament was secured by two sutures of fine silk, the infundibulo-pelvic ligaments being shortened in the same manner. In thus shortening the round ligaments within the pelvis, care was taken to insert the sutures from before backward, thus bringing the knot in front and well away from the tube, so that that structure might escape any danger that could arise from the proximity of this foreign body. The same caution was exercised in shortening the infundibulo-pelvic ligament, the loop being taken well away from the fimbriated extremity of the tube, nearer the pelvic wall.

The patient made a rapid and satisfactory convalescence, and in six weeks was back at her work, which she pursued without pain or interruption of any kind for five months, when she was obliged to retire because of a rapidly advancing pregnancy. She has since passed through a normal confinement, and is again at her work, well and strong. This patient declares that she is in better health than she has been since her menstrual life began, indeed, that she regards herself as being perfectly well and free from pain.

Case II.—Two months later I operated on the mother of this patient for double prolapsed cystic ovaries, without adhesions, with an equally satisfactory result. She, too, is a public dancer, and in spite of the arduous duties of these two women, they are absolutely free from pelvic trouble, and by careful bimanual examination I am unable to feel the ovaries of either one of them.

Case III.—K. C., married, 28. Came under my care Aug. 11, 1903. Family and previous history unimportant. The patient's menstrual history, beginning at her thirteenth year, has been regular and free from much pain. She has had no vaginal discharge. She has had no children and one miscarriage at the fourth month, which occurred in May, 1901. The patient is pale, thin, poorly nourished, extremely nervous and irritable. One year ago she began to suffer from pain in the back and lower part of the abdomen, particularly on the left side. This pain has grown more severe until at the present time it is almost unbearable, accompanied by nausea and faintness. The patient suffers from constipation and painful defecation, and coition has become almost impossible because of a sudden, sharp, sickening pain in the pelvis at that time, so severe as to almost produce fainting. Digital examination reveals an exquisitely tender, enlarged left ovary prolapsed into Douglas's *cul de sac*.

On opening the abdomen, this diagnosis was verified, the ovary was freely incised, a number of small cysts removed, and the wound in the gland closed with fine catgut sutures. The ovary was then lifted from the pelvis and held in its new position by means of the operative procedure which I have described.

The patient made an uneventful recovery, and now—nearly nine months since the operation—is entirely well, having gained in flesh and strength, and being entirely relieved of the severe pain, constipation and painful defecation which were making her life a burden to her prior to the operation. Her menstruation is normal and her marital relations are entirely satisfactory and free from pain. The ovary can no longer be felt on digital examination.

Case IV.—M. B., aged 25, married, was admitted to the Annex to Ward 23, Bellevue Hospital, Aug. 13, 1903. Her previous and family history are without bearing on her present condition. Her menstrual history began when she was sixteen years of age and has been free from irregularities except when interrupted by pregnancy. She has never had any children, but has miscarried twice about the third month of pregnancy, in May, 1901, and June, 1903. The patient has for two years suffered from pain in the pelvic region and lower part of the abdomen, most marked on the left side. She has suffered from almost constant nausea, and this with the pain has had a marked effect on her general health. She is the subject of chronic constipation, and the pain is greatly increased on defecation and coition. Her suffering has become so constant and severe, and her general health so much impaired, that she is unable to pursue her ordinary household duties longer. Examination reveals prolapse of both ovaries, which are enlarged and very tender.

Operation, Aug. 28, 1903. Several small cysts removed from each ovary and both ovaries restored to proper position in the pelvis by method described above. Patient made a satisfactory convalescence and is now apparently entirely well, is free from pain, her constipation and painful defecation and dyspareunia have disappeared, and her general health has been restored. On palpation no abnormal conditions can be found in the pelvis.

Case V.—C. J., 24 years old, married five years, was admitted to Ward 23, Bellevue Hospital, Sept. 3, 1903, with the following history: Has had two children, the first four years ago, and the last two years ago. Patient was well up to birth of her last child, two years ago, since which time she has suffered from pelvic pain and discomfort, the pain being more marked on the left side. Pain is not constant, but is present part of every day, provoked, apparently, by exercise or exertion of any kind, by defecation or coition. There has been almost constant nausea, with loss of flesh and strength, ten days of the last month having been spent in bed. Digital examination reveals retroversion of the uterus, with prolapse of both ovaries into Douglas's pouch. Uterus and ovaries restored to position in manner described, a cyst as large as walnut having been enucleated from left ovary. Patient made an excellent recovery, and declared herself as being free from pain during her convalescence.

At the present time the patient seems to be entirely well, her symptoms and physical signs pointing to no pelvic difficulty of any kind.

Case VI.—E. C., aged 23, married five years, was admitted to Ward 23, Bellevue Hospital, Oct. 5, 1903. Family and previous history negative. Patient says that she has never been pregnant, and that her menstruation has always been regular, there being present considerable pain for twenty-four hours prior to establishment of flow. Since October, 1901, she has had pains in the pelvis and lower part of the abdomen. The pain is intermittent in character, and at times very severe; seems to be provoked and increased by exertion of any kind, by defecation and coition, the latter being so painful as to practically prevent the proper establishment of the marital relations. Examination reveals a well-marked anteflexion, with prolapse of both ovaries in Douglas's *cul de sac*. (Fig. 2.)

Uterine canal dilated and curetted and packed with aseptic gauze, and the ovaries placed upon the pelvic "top shelf," as described. Patient has made an excellent recovery, and her general health, as well as her local condition, is greatly improved.

Case VII.—R. S., 23, unmarried, was admitted to Ward 23, Bellevue Hospital, Nov. 1, 1903. Patient has never been pregnant, and has suffered more or less at the time of her menstrual periods, the pain usually being for twenty-four hours before the flow is established, and less during the flow. She dates her illness from an attack of abdominal pain three years ago, which was most marked in the left hypochondriac region. Since that time she has suffered from severe cutting, nauseating pains in the pelvis, with severe pain on defecation, and marked constipation. Her general health has been poor; she is weak, nervous and irritable to a degree. She has been in three hospitals for treatment, but without relief. While in Bellevue, in August, 1903, for two weeks, she suffered so from painful defecation that it was impossible to get her to have her bowels moved, the patient lying to the nurses about the matter in order to avoid going to stool. Examination reveals double prolapsed adherent ovaries.

On opening the abdomen the ovaries are found prolapsed in Douglas's pouch, and buried in old adhesions. On the right side the appendix vermiformis is caught in the mass of adhesions, and this with the ovary and tube on that side is removed. The left ovary, when freed from adhesions, is apparently healthy, and the tube is patulous. This ovary is lifted from the pelvis in the manner described.

The patient had a painless convalescence, and her constipation was relieved. At the time of this writing, four months after the operation, the patient declares herself entirely well. Has gained in health and strength, and has no pelvic pain of any kind. The ovary cannot be palpated by digital examination.

Case VIII.—S. S., aged 23, married two and a half years, was admitted to Ward 23, Bellevue Hospital, Oct. 24, 1903. Family and previous history have no bearing on present illness. Patient's menstrual history began when she was fifteen years old, has always been regular and quite profuse, and has been accompanied by severe pain. She has been twice pregnant, the last pregnancy resulting in the birth of a child at term, in April, 1903, while the first was ended by a miscarriage, at six months, two years ago. Since the birth of her child, in April, 1903, patient says she has had severe, constant pain in back and lower abdomen on both sides, greatly increased by standing or walking, and markedly so on defecation. She suffers from nausea, loss of appetite, general weakness and great depression in addition to her pains, and her health and strength have become so impaired that she can no longer work and is forced to seek relief at the hospital. Her bowels are obstinately constipated. The patient is pale, thin, anæmic, nervous, and hysterical.

Physical examination reveals a slight laceration of the perineum, with a slightly enlarged, soft, anteverted uterus, with ovaries prolapsed in Douglas's *cul de sac*, and exquisitely tender to touch.

On opening the abdomen, the diagnosis was confirmed; both ovaries were placed on pelvic top shelf, according to author's method, a number of small cysts having been punctured in each. The patient made an uneventful recovery, and was discharged from the hospital well. At the present writing she has greatly improved in every way, all her distressing symptoms having been relieved.

Nothing abnormal in the pelvis can be discovered by digital examination.

Case IX.—R. S., aged 20, married, was admitted to Ward 23, Bellevue Hospital, Nov. 20, 1903. The patient is a Russian, who is unable to give an intelligent account of her condition except that she suffers from constant nausea and pain, especially marked on coition and defecation. She is poorly nourished, nervous, and anæmic. Physical examination reveals a retroverted uterus with prolapse of both ovaries in Douglas's pouch, the left ovary being somewhat enlarged and extremely tender. These organs seem to be adherent in their abnormal position.

On opening the abdomen this examination was verified, and the appendix vermiformis was found to be chronically inflamed and closely adherent to the right ovary and tube. The adhesions were so dense as to cause in their separation considerable injury to the right tube and ovary. These organs, together with the appendix vermiformis, were removed. The left ovary, which was deeply prolapsed in the bottom of the pelvis, was freed from adhesions, and laid safely upon the top shelf of the pelvis.

So far as her symptoms and physical signs are concerned the patient is now entirely well.

Case X.—S. M., aged 38, married 21 years, was admitted to Ward 23, Bellevue Hospital, Nov. 28, 1903. Patient's family and previous history have no bearing on her present condition. She says that since her marriage, which occurred when she was seventeen years old, she has menstruated regularly, except when this function was interfered with by pregnancy. Has always had pain, severe on the first day of menstruation, in back and lower abdomen and thighs. She has had three children and four miscarriages. Since Sept. 1, 1903, patient has had severe pain in region of right hip joint, in the lower abdomen, and in the pelvic and sacral regions. This pain is greatly increased on motion, defecation and coition, and is of a peculiar "sickening" character. It has become so severe that she has

been obliged to give up her work and come to the hospital.

Physical examination reveals a uterus somewhat enlarged and retroverted, with enlarged adherent right tube and ovary, and probable prolapse of the left ovary.

On opening the abdomen the right tube and ovary are found to be the site of extensive adhesions, the tube apparently containing pus. The appendages on this side are removed. The left ovary, normal in size and condition, is prolapsed into the bottom of the *cul de sac*. It is "shelved" in the manner described.

On Dec. 19, 1903, the patient left the hospital well and, according to her reports, remains in excellent health.

Case XI.—C. T., aged 39, married 13 years, was admitted to Ward 23, Bellevue Hospital, Dec. 19, 1902, with the following history: Family and previous history unimportant. Menstrual history began at fourteen. Menstruation has always been regular except when interfered with by pregnancy. It has been scant in quantity, the flow lasting but two or three days. There has always been pain for three days prior to the flow, and since Dec., 1903, for two hours before its establishment; severe pain in the lumbar and sacral regions and generally throughout the deeper parts of the pelvis. She has had three normal labors at term without complications or sequelæ. In Dec., 1902, the patient lifted an iron bed. This was followed in three days with severe pain on both sides, low down in the pelvis. Since this time she has suffered from severe nauseating pain in the pelvis, greatly increased at the menstrual periods and by motion, defecation and coition. For two months prior to her admission patient was practically invalided. Patient is thin, anæmic and badly nourished. Digital examination reveals a retrodisplaced uterus with an extremely tender mass behind the uterus in Douglas's pouch. On opening the abdomen both ovaries are found prolapsed and adherent below and behind a retroverted uterus. The adhesions about the tubes and ovaries are broken up, a number of small cysts removed from each ovary, and the tubes being uninjured and patulous, the uterus is restored to its normal position in the pelvis and the ovaries placed upon the pelvic top shelf.

On June 13, the patient was discharged from the hospital in a greatly improved condition and almost entirely free from pain. Physical examination showed the pelvis clear. She reports to me at this time that she regards herself as entirely well, having passed through a painless menstruation since leaving the hospital.

Case XII.—J. B., aged 27, single, was admitted to Ward 23, Bellevue Hospital, Jan. 4, 1903. Patient's family history is excellent. She has had the usual diseases of childhood. For several years she has been exceedingly nervous, with hysterical attacks, gastric disturbances, cardiac palpitation, and so forth. Her menstrual history began at sixteen. Until one year ago she has always been regular, flowing for six or seven days profusely, with well-marked backache. For the past year she has been somewhat irregular, menstruation being accompanied by severe frontal headache, dull pains in the sacral region, nausea, faintness, and great physical and mental depression. The pain in the back is referred to the sacrum and is continuous, but greatly increased on motion, standing or leaning over, and by defecation. Patient is chronically constipated, going from four to seven days without a movement.

Digital examination reveals a slightly anteflexed uterus, with both ovaries enlarged and prolapsed in Douglas's pouch, the right ovary lying below the left. On opening the abdomen this diagnosis is verified. The appendix vermiformis, being thickened and adherent to the broad ligament, was removed. A number of small cysts were removed from each ovary and the round ligaments and infundibulo-pelvic ligaments being shortened on both sides, the ovaries were "shelved" as described in the other cases.

On Feb. 17, the patient was discharged in excellent condition.

Some time might be profitably spent in the consideration of these twelve cases. In selecting them for a test of the operation, which I have proposed and described here, I have chosen patients having conditions typical of several varieties of cases of prolapsed ovaries. The first two cases occurred in public dancers, and it may be assumed that this occupation had some bearing on the etiology of the condition, and would surely furnish a fair test as to the efficacy of the operation.

The first patient had had three abortions; the third one abortion; the fourth two abortions; none of these patients having borne children at term. Such cases are very common in women suffering from prolapsed ovaries. It is easily understood that just so soon as the growing pregnant uterus becomes of sufficient size to make serious pressure on the ovary, caught between itself and the sacrum, sufficient irritation is produced to bring about an abortion. The successful delivery at term, of Case I, after the operation, both ovaries being involved, and she having miscarried three times prior to the surgical interference, seems to furnish a positive proof of the value of the procedure, beyond the mere relief of symptoms existing.

Case VI was sterile, but this sterility may have depended on the stenosis accompanying the anteflexion which was present, although the prolapsed ovary practically precluded connexion, because of the severe pain resulting from coition.

In Cases I, II, III and IV, there was prolapse of enlarged cystic ovaries without adhesions or displacement of the uterus, while in Case V a backward displacement of the uterus existed in addition to the double ovarian prolapse.

In Cases VI, VIII and XII, there was anteflexion, together with prolapse of both ovaries.

In Case VII there were general pelvic adhesions, with disease of one ovary and tube sufficient to demand their removal, and very extensive adhesions which had to be broken up about the ovary, which was permitted to remain.

In three of the cases it became necessary to remove the appendix vermiformis, in addition to the ovarian operation.

These cases have been chosen for a test of the operation because they illustrate admirably the many conditions complicating prolapse of the ovaries, as well as the various pathological changes dependent

upon these conditions. This work has been carried out along the lines of conservatism enunciated by me in a paper read some ten years ago before the New York Obstetrical Society, and with the hope that many ovaries, which might otherwise be sacrificed, may be saved to perform their functions to the comfort and satisfaction of the women who possess them.

8 West Thirty-sixth Street

UNUSUAL FORMS AND FAVORITE LOCALIZATIONS OF THE RHEUMATIC PROCESS.*

By J. SCHREIBER, M.D.,
AUSSEE-MERAN, AUSTRIA.

It is singular that so common a malady as rheumatism should give rise to such confusion and differences of opinion, not only in regard to its origin and nature, but also concerning its treatment.

Even leaving gout and acute articular rheumatism out of the question, the word rheumatism does not specify any clearly defined clinical entity, since some authors consider only affections of the muscles as coming within the limits of the term, while others include also the painful structures about the joints and the fibrous membranes.

A glance at the literature shows how great is the disparity of opinions. Cold, overexertion, irritation of the peripheral nerves, rapid changes of temperature, the attenuated poison of articular rheumatism, conjestion of the neurilemma of the motor and sensory nerves, trauma, and even unsuitable habits of life and heredity are all included in the etiology of the disease. Whereas Oppolzer views the malady as an inflammatory process without exudation, other authors consider rheumatism as a vasomotor disturbance. Leube and his followers speak of infection through bacilli. Prizbram considers muscular rheumatism as simply a muscular involvement attending articular rheumatism and not as a separate condition, while Lorenz states that the nature of the disease is so far unknown, and Senator calls the term rheumatism an inexact catch-all destined to receive all morbid processes in the muscles which cannot be more exactly defined. Leube has sometimes observed endocarditis together with muscular rheumatism; Strümpell denies any such connection.

Coming to the question of the pathological anatomy, some authors claim to have found a new formation of sclerotic connective tissue with secondary atrophy of muscle fibers and rheumatic nodes in the muscles, fascia, and tendons. Others deny the presence of pathological changes.

Views differ also in regard to treatment. Heat in the most varied forms is recommended (steam baths, hot-air baths, pine-needle baths, mud baths, slime baths, hot applications); acupuncture, injections of irritating fluids to produce phlegmons, massage, and medical gymnastics, salicylic acid and antipyrin, all have their adherents. Out of this labyrinth of conflicting opinions it is difficult to discover an issue and to follow the teachings of the two chief schools —those who believe in the infection theory and those who do not.

It is true that there are cases of muscular rheumatism accompanied by fever, but this symptom alone is not crucial, since it is well known that there are sensitive individuals who suffer a rise of temperature with any protracted pain, and, though occasionally some coincident circumstances bear out the idea of an infectious origin, a closer scrutiny of the facts impels to a different conclusion.

Permit me to describe briefly two cases in point observed about twenty years ago. I was called to see a young governess who had been in bed for several days with difficult and very painful respiration, and an elevated temperature. After careful ausculation it was possible to exclude any pulmonary or pleural affection, whereas pressure on the musculi serrati postici inferiores and on some of the intercostal muscles was acutely painful. Sure of the case I forcibly massaged the muscles invaded by the rheumatic process, with the result that the patient, with a deep inspiration, suddenly called out, "Thank heaven, I can breathe again!" Against my wishes she left her bed to take a walk in the garden, and what her friends had supposed to be pleurisy was cured in a few minutes. A year later I was at the bedside of a farmer's wife. The patient complained of pain in the posterior chest wall, just in the situation of the musculi serrati postici inferiores. Pressure on this spot caused acute pain and there was no doubt as to the diagnosis of muscular rheumatism. On examining the lungs, however, I found to my disagreeable surprise a well-marked pneumonia of the right side. Naturally, I did not massage, though that would certainly have relieved the rheumatism. The poor patient succumbed to the pneumonia and her death would surely have been ascribed to the mechanical treatment.

The causation of rheumatism by trauma must be denied on pathological grounds; and this theory serves only to make confusion worse confounded. Cases in which the patient believes that a long standing muscular pain is the result of some injury, usually reveal upon inquiry into the past some occasion on which sudden chilling followed overheating or overexertion, and when this history cannot be obtained it is to be assumed that the occasion of the rapid change of temperature has escaped the patient's recollection. An instructive case of this sort recently came under my observation.

A powerful man in the prime of life suffered for several years from a rheumatic process diagnosed as sciatica, severe enough to make walking, stair-climbing, and bicycle riding a torment. He ascribed the origin of his malady to overexertion while swimming. This possibility could not be excluded, but in the meantime months had elapsed and the enforced rest should have sufficed to relieve the pain and impairment of function. On examination I found a small, tender point at the edge of the sacrum corresponding to the gluteus magnus muscle, as well as tenderness about the trochanter (fascia lata). I then sought for the history of some sudden change of temperature to which, in the course of time, the patient had been exposed, and found that two years previously, in the spring, while in search of a summer residence, he had bicycled up a steep hill at the top of his speed, in order to catch a railroad train, and then, with only a light cloak for protection, had shivered in the car all night long. How often he

*Read at the seventy-sixth annual meeting of the Deutsche Naturforscher und Aerzte, in Breslau, Section of Internal Medicine, September 18-24, 1904.

might have previously exposed himself in this way after other bicycle rides he could not say.

Cases of muscular rheumatism come under observation which at first appear to be part of an articular rheumatism, but closer investigation reveals the fact that there is a combination of diseases and that the muscular affection may have even preceded the other, and that the disturbances are due to different etiological factors. This statement is illustrated by the following interesting observation: A perfectly healthy girl of nineteen years was in the habit of bathing daily in a cool mountain lake in Carinthia. On a chilly day she walked from the town at three hundred feet lower altitude to the lake, and, while heated from the climb, bathed in the water, which had a temperature of only 11° R. (57° F.). On the next day drawing pains were felt in the muscles all over the body, but no attention was paid to these. Some weeks later the family moved into a newly built house. The girl contracted acute articular rheumatism, involving all the joints of the body, including the maxillary and vertebral articulations, and rendering the patient nearly helpless. Mud baths at Carlsbad did not cause any improvement, but increased the sensitiveness to low temperatures. The following winter was a true martyrdom to the patient, who was confined to bed with increasing pain and loss of function. The following summer a mechanico-therapeutic course of treatment was recommended, and I treated the emaciated pacient, who could drag herself about only with difficulty on crutches, for two years, with massage and gymnastics, allowing intervals of rest. Her comfortless condition finally improved so that she could marry and become a happy mother. In this case the muscular lesion preceded the articular one and in the course of time became chronic. The articular rheumatism left incurable ankyloses in both elbows and in the right hip-joint. The muscular rheumatism was the result of the rapid change of temperature (bathing in the cold lake while overheated), and the articular rheumatism was explained by the removal into the newly-built house (bacilli). The fact is, there are border lands between articular and muscular rheumatism.

The case described also shows the superiority of mechanico-therapy over the method of heat application. The former generates warmth in the interior of the muscles, the dormant vitality is stimulated, and the normal relationship between will and muscle fiber is restored.

To this infrequent combination I should like to add the following unusual types of rheumatism, which have to my knowledge so far received but little attention in literature.

1. Rheumatism of the costal periosteum, of the costal arch, of the sternum, the ensiform process, and the hollow bones—diseases which, as the following observation teaches, are wrongly interpreted. In 1902 I became acquainted with the vigorous and otherwise perfectly healthy wife of a colleague who was accompanying her sick mother to my institution. Only by accident did I learn from the husband, who was present, that his wife had for years been suffering from a troublesome pain in the sixth and seventh ribs, which was very annoying, but had been treated by many physicians without avail. He had not spoken of it before, because he considered his wife's ailment incurable. Through former experience I had become familiar with rheumatism of the periosteum. My suspicion was confirmed. On examination I found that there was no swelling of the bone, and I at once began active mechanical treatment, which was continued for four days, at the end of which time the pain had completely disappeared and never recurred.

2. Rheumatism of the diaphragm. The disease manifests itself by dyspnœa and labored breathing, although the lung is healthy, the heart is normal, and there is no rheumatism of the accessory muscles of respiration. Mechanical treatment of the diaphragm is difficult and one must be content with the application of the less rapidly effective faradic current, applying the electrodes under the costal arch as well as circumstances allow.

3. Localized rheumatism of the tuber ischii and of the ligaments of the pelvic outlet. Such rheumatic processes sometimes persist for years in spite of all efforts to cure them by other means, but promptly yield to mechanical treatment.

4. Isolated unilateral rheumatism of the masseter. Wrong diagnosis of this condition leads to ineffective or even injurious treatment. In August of this year I visited a friend and found him with his face bandaged and complaining of pain in the lower jaw. He had been told to apply a dressing of aluminum acetate and to take only fluid nourishment. The lower jaw showed neither redness, swelling, nor heat, but there was severe pain on pressure over the masseter. This muscle was energetically massaged, the dressing discarded, and the patient told to chew solid food, with the result that he was cured the same day.

To the unusual types I should like to add the favorite seats of rheumatism: (1) The supraspinous fossa of the scapula; (2) the protuberance of the occipital bone; (3) the linea semicircularis of the occipital bone; (4) the galea aponeurotica of the calvarium; (5) the temporal muscle and its tendon under the zygoma; (6) the outer border of the scapula and the tendons of the teres major and minor muscles at their insertion into the humerus; (7) the sacral origin of the sacro-lumbalis muscle; (8) the sacro-lumbar fascia; (9) the origins of the glutei muscles from the sacrum and the pelvic brim; (10) the muscles originating from the pubic bone; (11) the muscles, tendons, and ligaments attached to the external and internal condyles of the femur; (12) the muscles attached to the fibula; (13) the tendons and ligaments attached to the external and internal condyles of the humerus, the radius, and the ulna.

A knowledge of these favorite sites is of importance for the physician, since it affords valuable assistance in making the differential diagnosis between rheumatism and the pain of neuritis, neuralgia, and neurasthenia, which require widely different forms of treatment.

I am fully in accord with Senator's view, that rheumatism is the result of disturbances of circulation, which, in a short time, correct themselves. Were this not so humanity would be in a bad way, and as long as it remained customary to treat fresh cases of rheumatism with fomentations, salves, rest, and catskins, there would be countless cripples drag-

ging out a pain-tortured existence. Sometimes the circulatory disturbance does not correct itself and chronic rheumatism develops, which involves new portions of the body and increases the number of functional derangements. Such patients do not recover spontaneously, and can be cured only by mechanico-therapeutics, often requiring months and years.

At the beginning every sufferer from rheumatism has his recovery in his own hands; he needs only to carry out the movements that give him pain. A poor carpenter who forces himself to saw and plane with rheumatic arms does his work at the expense of pain, but after a short time this disappears. Only the next morning, after hours of rest, does the pain recur again, to be dispelled by work, until finally it does not return. The poor workman has unconsciously carried out the treatment of modern mechanico-therapeutics. Had he been wealthy, the advice of some doctor still behind the times might have impelled him to place his arm in a sling, to apply ointments and fomentations, to make a fruitless journey to baths, and to have joined the unfortunate ranks of the chronic rheumatics.

Thirty years ago I learned by chance that movement is the best cure for chronic rheumatism. I sent to Vienna a horse that had limped for months, owing to rheumatism of the shoulder, in spite of treatment with all sorts of ointments, intending to have the animal sold as a work horse. The coachman who was to ride the horse was allowed three days for the journey. Out of impatience to reach the capital, he forced the pace and covered the distance in two days. On arrival in Vienna the horse no longer limped, and was brought back home completely cured, so that it did perfect service for years.

Every horseman knows the rule not to stable horses immediately on their return from exercise. They are rubbed down with straw (so that the peripheral vessels shall not contract too rapidly), are blanketed and walked up and down for some time before being put into their stalls. Similar rules would be of advantage for human animals.

As the result of my thirty years' experience I draw the following conclusions:

1. The term muscular rheumatism should be dropped in the interest of clearness and simplicity, and the unqualified term rheumatism substituted for it.

2. "Rheumatism" should be understood as meaning all the affections, produced by rapid changes of temperature, in the structures attached to the limbs, the periosteum, and in fibrous membranes.

3. Those disposed to rheumatism do not from a prophylactic standpoint need to dread uniform cold, even if intense, but rather warmth, especially that caused by muscular effort, suddenly followed by rest and cooling off.

4. The most rapid and reliable remedy for recently acquired rheumatism is muscular exercise. The patient should boldly perform the movements that cause pain. Articular rheumatism should of course be carefully excluded.

5. Chronic rheumatism can be cured only by mechanico-therapeutics, in which active and passive movements play the chief rôle.

6. The clergy, school teachers, and foresters should add this simple doctrine of muscular rheumatism to their stock of hygienic lore, in order that they may be able to instruct the people in regions without physicians and so preserve many from serious illness.

THE SPECIFIC TREATMENT OF TYPHOID FEVER.*

By JAMES MORRIS HACKETT, M. D.,
CHAMPLAIN, N. Y.

I WISH to call your attention to a method of treatment of typhoid fever which I venture to call specific. I have evolved this treatment from fifteen years' experience with this remedy in the treatment of typhoid fever, gradually developing each stage until I have reached a degree of certainty as to its efficacy.

While I am aware that up to the present time no remedy has ever been accepted as a specific in the treatment of typhoid fever, I wish to make the statement here this evening in the presence of this distinguished gathering of the medical profession, that mercury in the form of blue mass and calomel is a true specific in the treatment of typhoid fever.

Mercury when given into the human system is taken up by the circulation and distributed throughout the entire economy; this enables the mercury to come in contact with the typhoid bacilli, wherever they may be found, and to attack and destroy them, possibly having somewhat the same fatal action on the bacilli in the system that bichloride of mercury has outside the human system. I have demonstrated many times the fact that when blue mass was given to a patient suffering from typhoid fever, within from four to ten days subsequent to the beginning of the administration of the blue mass, the typhoid bacilli are no longer active in the system. This fact is signified by a gradual reduction of the body temperature to normal, and a general sense of well being of the patient, followed by a rapid convalescence.

In the short time accorded me this evening I wish to outline the mode of treatment, and exhibit a few temperature charts of recent cases. The treatment consists of giving mercury in the form of blue mass to the extent of one or two grains every three hours from the time the case comes under observation until the constitutional symptoms of mercury, viz., soreness of the gums, is noticed. An initial dose of five or ten grains of calomel is given as well, followed in a couple of hours by a Seidlitz powder, or two drachms of Rochelle salts, unless hemorrhage or grave diarrhœa is present. If constipation is the rule during the progress of the disease, five grains of calomel may be given once every day. Calomel is not as safe as blue mass to impregnate the system, as it is apt to cause grave diarrhœa with tormina and tenesmus and even great prostration. Whether the bowels are constipated or loose, the rule is to give an alkaline cathartic every morning during the course of the fever, a Seidlitz powder or a teaspoonful of Rochelle salts, unless there is hemorrhage or some other complication to contraindicate its use.

It is usually the case in typhoid fever that the patient is unable to sleep; this is due, perhaps, to the presence of the typhoid bacilli in the blood and

* Read by invitation at a meeting of the Medical Society of the County of New York, September 26, 1904.

should be met with an opiate. It has been my rule for years to give opium in one form or another in sufficient amount to ensure the patient good rest both day and night. Rest means repair, and this is what is required to procure the best results. Opium likewise retards the peristaltic action of the bowels,

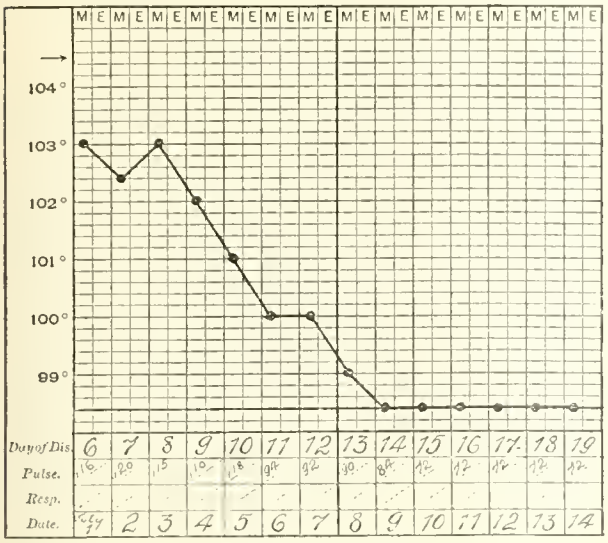

Chart 1.—Wm. R., aet. 45 years.

thereby, no doubt, lessening the danger of hemorrhage and perforation from ulceration; and should hemorrhage occur, morphine (hypodermically) should be given to the extent of keeping the bowels quite free from peristaltic action. An enema of water and glycerine would be indicated to bring about a stool.

In regard to diet, I established a few years ago a standard diet of milk and water in equal parts, a tumbler full, or such a portion of it as the patient could take, every two hours, given ice cold. I observed that this cold nourishment assisted materially in reducing the temperature. If this cannot be borne by the stomach after a fair trial, give some light farinaceous gruel or peptonized milk. I urge my patients to drink water as freely as possible all during the course of the disease; it acts as nourishment and retards the tissue waste induced by the fever. Watermelon I have found to be harmless and to prove a great comfort to the patient, filling a long-felt want in the diet treatment of typhoid fever.

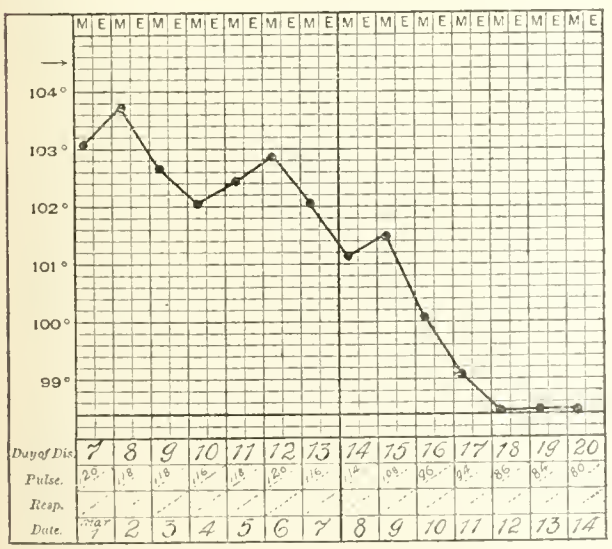

Chart 2.—Thomas L., aet. 16 years.

This treatment by mercury obviates altogether the necessity of the cold bath. However, when the conveniences are at hand, if the temperature is above

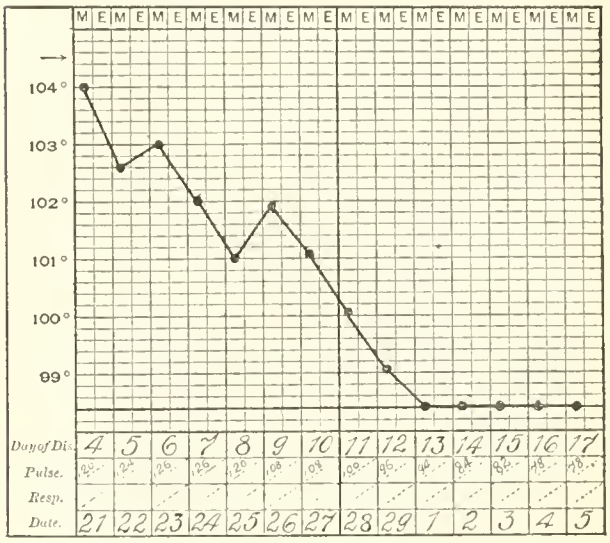

Chart 3.—Madeleine B., aet. 8 years.

102.5° the graduated cool bath is used for a few days as an adjunct to the treatment. It is a fact that cold retards the proliferation of germ life, therefore, in the early stage of typhoid fever, before the mercury has control of the bacilli, and in order to save the tissue waste of a high temperature, I use the graduate cool bath, or a sponge bath with alcohol and water, equal parts, night and morning, for about a week. This is agreeable to the patient, and, no doubt, of great benefit in bringing about a healthy condition of the system.

I have had many cases of typhoid fever, however,

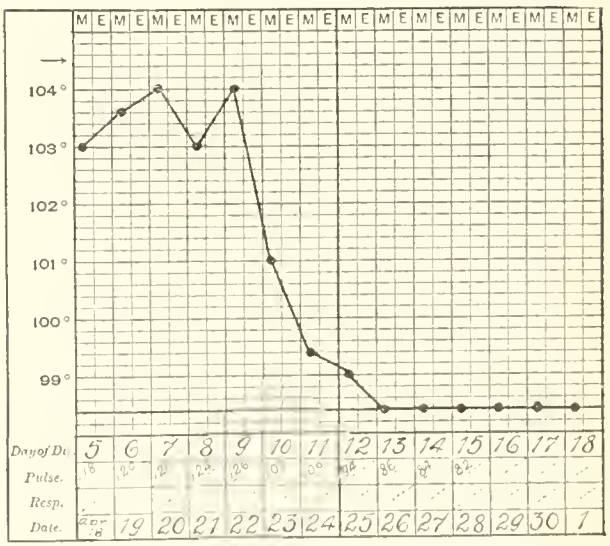

Chart 4.—Edward L., aet. 17 years; there were fourteen hemorrhages between the fifth and tenth days of treatment.

since using the mercury treatment, that were not bathed or sponged, and without any mortality. Two of the patients, whose temperature charts are exhibited this evening, were not bathed or sponged.

As a result of this treatment I have observed:

1. In all cases of typhoid fever mercury is well borne by the system; it required more mercury to

get the constitutional symptoms of tenderness of the gums when typhoid fever was present than under any other circumstances.

2. In the administration of blue mass in cases of typhoid fever that gradually, as the system becomes impregnated with mercury, just so gradually are the bacilli disappearing, so that when the system is impregnated with mercury to the extent of a slight soreness of the gums the bacilli are no longer active. This is signified by a gradual reduction of the temperature to normal and a rapid convalescence.

3. With the use of mercury the patient's blood is in a more healthy state; mercury maintains the red corpuscles of the blood, and accordingly the system does not fall into that state of grave anæmia so common to the disease under other or no treatment.

4. The patient may begin taking solid food as soon as the temperature is normal without danger of relapse. This I attribute to the healthy condition of the blood due to the action of the mercury in the system.

5. A few days after the beginning of the administration of mercury in the treatment of typhoid fever, the tongue gradually becomes moist. The breath gradually becomes less fetid, indicating a more healthy condition of the stomach, and there is a desire on the part of the patient to take the nourishment described. The stools also gradually lose their fetid odor. I have not had a dry tongue continue beyond three or four days after treatment was instituted since I began the use of mercury in this disease.

6. The temperature of the patient treated with mercury in typhoid fever does not become subnormal after fever drops. The reason I ascribe for this is twofold: (*a*) We get control of the disease before the patient falls into a very low physical condition, and (*b*) the mercury preserves and increases the red corpuscles of the blood, tending to maintain the physical standard.

7. It is unnecessary, unpardonable, and unscientific to salivate a patient when using mercury in the treatment of typhoid fever, but I have yet to observe any ill effects of the slightest nature from the use of mercury in the system to the extent only of the soreness of the gums.

I wish to call your attention to four temperature charts of recent cases, with all but one of which I have a certificate from the State Board of Health, certifying that the Widal reaction was present. The other specimen was mislaid in the laboratory at Albany for three weeks, and then proved negative. In this case, however, a young man of seventeen years had fourteen bloody stools from the fifth day of treatment until the tenth. Please notice by these charts that three weeks cover the whole period of illness, and, besides, that the third week is a week of convalescing.

In conclusion I wish to add that this paper may throw light upon the discussion that took place over the merits of the Woodbridge treatment, when we consider that among other drugs used in his treatment calomel was included in prescription No. I.

Mr. Chairman and gentlemen, I wish to thank you for the great pleasure and the distinguished honor of meeting you to-night, and may I hope that the discussion of this topic will be of benefit not only to us, but to those to whom we are called upon to minister. I ask your co-operation to further develop the treatment for typhoid fever, which I have here advocated.

WHY RAILROAD AND SIMILAR CORPORATIONS LOSE THEIR DAMAGE SUITS.*

A CRITICISM OF PREVAILING METHODS.

By JOHN PUNTON, M.D.,
KANSAS CITY, MO.

MEMBER AMERICAN NEUROLOGICAL ASSOCIATION; NEUROLOGIST TO ST. LOUIS AND SAN FRANCISCO RAILROAD, SOUTHERN KANSAS RAILROAD, ETC.

It is not usual for a physician to undertake to instruct the officials of a great railroad system how they should manage their business affairs. It may, therefore, seem somewhat presuming, if not absolutely impertinent, on my part to attempt to criticise prevailing methods, or be so bold as to assume the right to tell them why they lose their damage suits. Such an assumption at once questions my qualifications for such a task, as well as my motives for its necessity, or even the good which may accrue from its public discussion, all of which is pertinent and in strict accord with practical ethical court procedures.

It will be my purpose, however, to answer these questions in the course of my remarks to the satisfaction, I trust, of those interested, and in the hope of demonstrating not only some of their causes, but also needed reforms in dealing with these medico-legal problems.

No thoughtful person can fail to observe the marked increase of litigation of all kinds during the past decade; indeed, the tendency of the age in which we live is to sue for damages on the slightest provocation. It is only a few years ago, however, when the bulk of lawsuits were confined to railroad and insurance companies, but to-day no corporation or private citizen is exempt from its pernicious influence. Moreover, the successful practice which has attended its followers has proven to be a great temptation for the development of a class of lawyers who have earned the unenviable reputation of being designated by the term "snitch," which in medical parlance corresponds to the term "quack" or "charlatan." These miserable scamps rush to the scene of an accident and enforce their services upon the injured on the contingent fee plan, being very careful to enlist the services of some equally unscrupulous person, who having managed in some way or other to possess a medical degree, is thereby allowed to answer to the name of "Doc" or "Doctor," and whose opinions in courts of law are accepted with as much respect and sincereness as the most strictly ethical member of either of these noble professions. Contemporaneous with the "snitch" lawyer and the "quack" doctor, undesirable citizens of another class are rapidly growing in numbers who are also closely identified with the sharp methods and nefarious practice of these irregular professional contemporaries. These correspond to those who practice the deceptive art in relation to alleged injuries, and who invent various novel tricks and devices for the sole purpose of defeating the most thorough and painstaking medical examination.

The marvelous ingenuity displayed at times by these crafty malignerers in practicing their decep-

* Read before the Frisco R. R. System Surgical Ass'n, Altman Building, Springfield, Mo., May 24, 1904.

tion and the great success which attends their efforts at the present time should certainly tend to stimulate us to more effective service in exposing their fraudulent methods. That medical malingering constitutes one of the most formidable evils of the present age is well understood, but its peculiarly successful practice would seem to reflect upon the ability of the medical practitioner to detect its fraudulent character. Unfortunately, it is not uncommon to find well-known, and even reputable, members of both the legal and medical professions lured by these professional barnacles into the temptation of loaning their services in cases of doubtful merit, thus lending themselves and their influence, either through sheer ignorance or want of conscience, to not only unethical but the sharpest forms of fraudulent practice. Hence members of the regular medical profession are often known to place themselves open to severe and critical censure by their thoughtless or intentional actions, while their motives in such a case are readily detected, and by their more strictly ethical professional brethren are at once inaudibly classed where they belong, viz., with the charlatans.

Such disgraceful proceedings have been the means of lowering the value and dignity of both these noble professions in public esteem, but more especially does it reflect upon the integrity of the medical profession, whose opinions in courts of law are now subject to so much distrust, besides being ridiculed and even treated as a standing joke by the general public.

These facts, when associated with the universal intense prejudice which exists toward corporations of all classes by the general public, readily offers some good reasons why railroad companies lose their damage suits, for it must be confessed that when a railroad company, or any other corporation, is compelled by force of circumstances to meet in courts of law a trio of dangerous elements like those of a "snitch" lawyer, a "malingerer" and an "unethical doctor," and attempt to vie with them and their shrewd, malicious practices, it means certain defeat to those who oppose them.

That a combination of this kind, in part or whole, is found to exist in the very large majority of damage suits in which the railroads fail to obtain a favorable verdict is common knowledge, for experience proves that it is not the conditions in which undoubted organic changes are present that result in litigation, but those in which the evidence of an injury is largely subjective in character, and therefore readily assumed or simulated, and consequently more subject to doubtful inquiry. Moreover, when this dangerous combination is assisted by the active participation of some well known and supposedly ethical members of either the law or medical professions, their cause is greatly strengthened, for what may be lacking in their combined efforts to prove the actual liability of the railroad company the inherent public prejudice, which also extends to the jury, more readily supplies the missing link which completes the chain of evidence sufficient to establish the conviction of culpable neglect or responsibility on the part of the railroad officials, and an unfavorable verdict is the inevitable consequence.

Having for many years been called upon at different times, both at home and abroad, to serve in the capacity of a medical witness in damage suits, both for and against railroad, insurance and other corporations, beside individuals accused of crime and other misdemeanors, as well as pass upon the mental capacity of those suffering from various brain diseases and the ability of such persons to perform certain duties, such as make a will, sign a contract, and similar transactions, exceptional opportunities have been afforded me to become more or less familiar with the various methods pursued in the different courts in which the cases were tried, as well as recognize some of the prevailing evils which affect our courts and the present jury system. In this connection it affords me great pleasure to note that during the many years I have been associated in this way with our courts of law the utmost courtesy and kind consideration have always been accorded me by the court officials, and I am firmly convinced that they are much more ready to learn the truth than falsehood from any witness, and from the maze of confusion which ordinarily attends the average medical court examination they readily discern the sterling qualities of honesty, truth and sincerity of purpose when forthcoming from the medical witness, even though they be powerless to change the prejudicial convictions of the jurymen.

Moreover, in my extensive dealings with the officers who represent the various corporations, whose business, like that of a large railroad system, necessarily renders them more liable to become entangled in lawsuits involving medico-legal problems of the highest order, to their honor let it be said that not once have they asked me to favor them unduly or become biased in my judgment in their behalf. My instructions have invariably been to make a thorough examination of the patient and report the actual conditions as they exist to the best of my ability. That this, however, is contrary to general belief and opinion is very clear, for my experience proves that an effort is made in the large majority of damage suits in courts of law to show the jury that not only are the medical employees of railroads and other corporations necessarily biased in their opinions favorable to the company, but are even instructed and coached in regard to their testimony, thus attempting to prove that their evidence lacks truth and destitute of all honest intention, beside implying that such employees are simply assuming the "role" of bought witnesses.

This again furnishes another good reason why railroads lose their damage suits, for it cannot be denied that, notwithstanding the honest purpose of such a medical witness or his special qualification to serve in that capacity, the mere fact of his being an employee or furnished with a pass on the railroad is sufficient evidence, according to many unscrupulous lawyers, to cast a slur upon the integrity of his motive to tell the truth upon the witness stand.

A common misconception is also prevalent, especially among lawyers, to the effect that the conflicting testimony of the physicians is the responsible agent for many of their failures to win damage suits. It would require too much time to refute this charge in detail, and perhaps in a few cases such an accusation could be successfully sustained, but in the very large majority of cases my experience proves that it is not so much the fault of the doctors as the lawyers who question them that cause not only the fail-

ure, but also the medical confusion, as medical science is much more exact than they are wont to believe or allow. This therefore brings me to the very climax of my theme, for, in my judgment, it is not the doctor, but the want of medical knowledge on the part of the lawyer that tries the case, that not only results in the loss of the suit, but also proves so often disastrous to the railroad treasury.

No medical man who has had experience in our courts of law could fail to recognize the woeful ignorance of medical science that the average lawyer betrays. Without attempting to underrate their special technical knowledge of law or their educational advantages in other departments, I do not hesitate to aver that the medico-legal department of the average railroad is the weakest link in the great chain of all their mighty connections, and that lack of thorough organization of this important department is the most plausible of all the reasons that can be assigned for failure to win their damage suits. To prove the truth of this assertion, watch carefully the proceedings associated with the medical witnesses next time you attend court, and you will discover that it is the rarest exception that a lawyer can take advantage of a manufactured answer to his question by a medical man, when he desires to prevaricate or evade the truth. Many an answer given in this way is a medical contradiction, and often implies to the scientific physician an impossibilty, and out of all keepng with clinical experience and medical knowledge, yet the fictitious answer is allowed to go to the jury as a correct solution of the problem, because the lawyer fails to recognize its deception, as he is unversed in medical literature, and consequently cannot interpret its false and unsound premise. What physician, for instance, would accept without treating it as a joke the answer to the question, "Doctor what was your diagnosis of the case?" Answer, "Traumatic injury with general results." This was a case in which a quack doctor claimed that his patient had sustained permanent injuries, as the result of a slight accident. The lawyer representing the corporation ranks high in his profession, yet he failed to see the absurdity of this answer, and was therefore unable to demonstrate to the jury its fallacy. It is needless to say, he lost the suit, and the company was assessed several thousand dollars damages.

A short time since, a doctor in good standing claimed that the person he was defending had paralysis of nearly all the cranial nerves, but upon cross examination, said that the fifth supplied the face, neck, and upper extremity with motion. The lawyer representing the railroad company failed to recognize the absurdity of this answer until his attention was called to it, but not before the witness had been excused from the witness stand. Moreover, the plaintiff did not suffer from either motor or sensory paralysis, still he secured a verdict for $10,000.

As the result of a slight fall on a sidewalk, a doctor recently claimed on the witness stand that the heart had been displaced downwards two inches to the left, while three reputable physicians testified that the heart was not only normal, but the alleged displacement was an utter impossibility when all the circumstances were duly considered, yet this person secured a verdict for several thousand dollars.

Some time ago I was called as an expert to examine and testify as to the mental capacity of a man suffering from paralysis agitans, and his ability to sign a contract. After examination, it was my opinion that he was mentally competent. It seems he had failed to live up to a contract, and was sued. The evidence proved that he had always been a shrewd business man and acquired considerable wealth.

An old physician being called to the stand, testified that during his twenty years' practice in the neighborhood (a sparsely settled district of Missouri) he had seen at least a dozen cases of paralysis agitans among the inhabitants which had rendered all of them "*non compos mentis.*" The lawyer for the plaintiff, however, failed to recognize the absolute contradiction to medical experience and knowledge contained in the statement of the doctor, and allowed it to go to the jury unchallenged, which resulted in a verdict favorable to the defendant. These examples are cited simply to emphasize the fact that the lawyers themselves are unable to recognize the educational weakness of the medical men, whom they undertake to examine for the purpose of extracting the actual truth.

What is, therefore, needed, in my judgment, is a closer bond of union between the lawyer and the doctor, a more harmonious relationship between the legal and medical departments of the railroad; in fact, the organization of a medico-legal strategic board, composed of both lawyers and doctors, in connection with every great railroad system, whereby the lawyer can become better acquainted with general and special scientific medicine, and the doctor more thoroughly versed in practical legal technical matters. Only in this way can the legal and medical departments work together as a unit, as there should be a common understanding between the two, for at the present time these are carried on as distinct and independent departments, when, practically speaking, in courts of law, their interests are one, having the same aim and object in view, viz., to demonstrate to the jury the actual truth concerning the case at issue.

Every damage suit of large proportions, at least when there is the slightest suspicion of fraud or deception, should be fought and won before it reaches the court, on the same principle that the strategic board belonging to the War Department at Washington not only prepares plans for war, but fight battles and win victories before the actual conflict occurs. The same idea is implied by the insurance companies, who not only undertake to protect physicians from law suits, but are prepared to fight their battles in courts of law, with every assurance of final victory.

As it now stands, the medical department of a great railroad system is composed of the busy medical practitioners scattered along the steel highway, commanded by a chief surgeon, who, in addition to his multitudinous duties, is expected to take full charge of the hospital service, with all of its business ramifications, beside perform the major operations and the subsequent care and treatment of all those employees whose condition requires them to be confined in the large general hospital belonging to the company, as well as testify in court as an expert, when he is called upon. It is practically impossible for any chief surgeon thus situated to devote the time and attention that it justly demands

to the solution of the many intricate medico-legal problems that naturally arise in connection with the injured who resort to litigation for their recompense. Moreover, the local surgeons, at his command, are often called suddenly to the witness stand to answer the most difficult medico-legal problems without the slightest preparation. The fault of such a method, as well as its unfairness, easily explains why railroads lose their damage suits.

In addition, we also find the legal department no better prepared to grapple with these same problems, for it is not uncommon to find a firm of local lawyers residing in the town in which the case is tried, representing the railroad company, enforced to conduct a law suit in which several thousand dollars is involved, and in which medico-legal problems of the highest order are concerned, and yet they are destitute of the slightest assistance from their legal or medical headquarters. To their honor, however, let it be said that the shrewd and able manner in which they often conduct such difficult cases command the admiration of those interested, even though their lack of medical knowledge cause them to lose the suit.

Another reason why railroad corporations lose their damage suits was beautifully illustrated recently when the state attorney of one of the leading railroads refused to listen to the advice of an equally prominent doctor, in reference to a case which was attended with dangerous elements to combat in a court of law.

The lawyer admitted that the man was injured, thereby conceding the lawful liability of the company, and upon examination, the doctor claimed that some of the symptoms were the result of the accident, while others were simulated, and advised settlement of the claim, which could be done for less than $3,000. The lawyer, however, scorned the idea, and in his confidential pride said that he did not propose to be stampeded by any such advice, and would rather fight it out in court to the bitter end, which was eventually done to the tune of a verdict for a fraction less than $15,000, and which, unfortunately for the company, still stands against them, as a new trial has already been refused.

The only remedy, in my judgment, for this lack of organized effort, and one which will fuse the interests of all concerned, is the establishment of a *medico-legal department,* composed of alienists, neurologists, physicians, surgeons, and lawyers of undoubted reputation, skill and experience in their respective specialties, whose combined efforts should constitute a strategic medico-legal board, the duties of which should be to furnish and prosecute plans of defense against the inroads of fraudulent claims upon the railroad company they represent. This should be a separate and distinct organization from the present employees' hospital association, but should work in harmonious relationship with it, and its work thus becoming a safeguard to not only the railroad company, but also its numerous employees. Such an array of combined talent, working in harmony, could not fail to accomplish much good in both the equalizing of *just* claims as well as curtailing the great success which now attend the efforts of malignerers in our courts of law, while the expense incurred in the maintenance of such a board of experts would not begin to approach the amount of money now paid annually to fraudulent claimants. This method has already, to a very limited extent, been inaugurated upon the great railroad system we represent (the Frisco) by recognizing the special departments of medicine on its medical staff, and under the able direction of Dr. G. W. Cale, the Chief Surgeon, has already accomplished very substantial evidence of its power to yield financial results favorable to the company, for no railroad officer can become familiar with the celebrated "Hoskins" case of Fort Worth, Texas, without recognizing the value of medical expert opinion.

This, as you know, was a deliberately planned scheme to defraud this railroad company of $75,000, and an actual judgment had been secured by the malignerer for $35,000, even in spite of the fact that the fraud had been detected by Dr. Cale and myself, and had even been exposed in no uncertain way in my testimony on the witness stand. That this actually led to the confession and conviction of "Hoskins," as well as setting aside the verdict to the financial benefit of this railroad, I think you will all agree, and simply emphasizes the strength of my position when I advocate the necessity of the establishment of a medico-legal board of experts. In the vast majority of these damage suits, the same problem presents itself for solution, viz., the nature and extent of injury to the nervous system. This takes precedence of all other questions associated with such litigation, and such being the case, it is, in my judgment, not only possible, but absolutely certain, that this apparently complicated subject can be reduced to a definite number of intelligent facts, which, when duly presented, would not only appeal to, but come within the comprehension and understanding of, the average juryman, thereby enabling him to perceive the slick tricks and fraudulent character of many claims which he is called upon to pass final judgment.

The gross injustice which now prevails, in not allowing proper surveillance and examination of those claiming damages, is also responsible for many miscarriages of justice. That popular opinion inclines to the belief that railroad companies pay too little heed to the protection of human life, in order to enlarge their yearly dividends, is also a mistaken idea, and not in accordance with the truth. The facts are, there never was a time in railroad history when so many safeguards were furnished the human passenger. Notwithstanding all the improvements which modern invention supply, and the numerous safety devices for the good of humanity, which every first class railroad system has added to its equipment, it is a notable fact, according to the information furnished me recently by the vice-president of one of our great railroad systems, that during the past decade, in spite of all the many expensive instruments employed to protect passengers from injury on our railroads, damage suits have increased more than sevenfold during this period. What a sad commentary on our medical and legal professional ability, for it is only fair to presume that if the many frauds were detected and exposed in our courts of law, that appear there for legal adjudication, malignerers would not do such a thriving business.

That certain lawyers are known to refuse the truth when forthcoming from medical men, is also true,

hence we find them insisting upon the result of the examination of their client being made known prior to the medical witness being called to the witness stand, and if the medical opinion is not in accord with the view of the lawyer or his plan of defense, the medical witness is excused at once from testifying, because the lawyer does not wish any testimony to reach the jury that might injure his case, and thus the truth is often concealed or rejected.

It is also not uncommon for physicians to claim that railroads deserve to lose their law suits because of the niggardly manner in which they treat and pay medical men for their professional services. That railroad officials often treat medical men in a shabby manner, and fail to recompense them in proportion to the time and value of their services, is quite true, but this should never militate against their telling the truth on the witness stand. Moreover, it is a common observation that railroad officials pay too little heed themselves to local law or city ordinance, whenever an infringement of these are necessary to carry out to final completion a certain definite plan which adds to their convenience and financial profit; hence these shortcomings lend additional reasons why they lose their damage suits. Recognizing, however, that there are many faults on all sides, it is very clear that these will never be adjusted until some practical move is made in that direction, for it cannot be denied that the time is at hand when reforms are greatly needed relative to the solving of the many medico-legal problems which arise in connection with railroad injuries.

Admitting that the plan suggested for its relief is largely theoretical and open to just criticism, for no doubt there will be those that can see no good accruing from such a course, as such critics can always be found ready to attack any step in advance, even though they be wholly incapable of offering any better assistance. That the organization of a medico-legal strategic board of experts is perhaps not altogether ideal and without any flaws, yet its practical operation would certainly be a vast improvement on the faulty methods now in force. The time, however, may come when the physician employed on either side can take the case under advisement, and consider all its details impartially and dispassionately, thus conferring together in such a manner as to reach a mutual agreement, which can thus be referred to the court or jury. But in the absence of such an ideal method, the plan herewith outlined at least has the advantage of not only favoring the detection of fraud in all its forms, but also tends to overcome the many errors that now exist between both the lawyer and doctor, which again would also duly enlighten the citizens comprising the jury.

In order that my motive for presenting this subject may not be construed as having a mercenary or commercial object, I desire to state that under no consideration would I accept a position on this board were it offered me, but believe that the salaries attached should be sufficiently large and remunerative to command the services of the most able experts, who should devote their sole time and attention to this work. In its more matured state, the plan suggested would also embody features looking toward the enactment of laws having for their purpose the more just and equable disposition of such cases, as well as remedy many of the existing evils with which they are now surrounded.

It is to be hoped, therefore, that the plan advised will be duly considered by the proper officials, and if deemed worthy and expedient, will early inaugurate its practical operation. Such a course, in my judgment, will not only benefit the railroads and other corporations, but also all those who are in any way associated with damage suits arising from railroad and other forms of injury.

Altman Building.

ACUTE TETANUS CURED BY INTRANEURAL INJECTIONS OF ANTITOXIN.

By W. SCOTT SCHLEY, M.D.,
NEW YORK.
URGEON, TRINITY HOSPITAL; ASSISTANT SURGEON, ST LUKE'S HOSPITAL.

In the last few years a number of valuable articles upon the treatment of tetanus have appeared and a sufficient time has elapsed since the advent of the serum therapy of the disease to draw conclusions of some value. The generally accepted mortality under the symptomatic plan of treatment is from 80 to 90 per cent. in the acute form and 25 to 40 per cent. in the chronic form of the disease.

The use of antitoxin (by various methods) appears to have reduced the general mortality to between 40 and 50 per cent.—of the acute form to about 70 per cent., and the chronic to from 20 to 25 per cent. Packard and Willson, in a study of 1,216 cases of tetanus treated with serum found an average mortality of 42.2 per cent. Moschowitz, in a collection of 461 cases treated with serum subcutaneously and intravenously, found an average mortality of 40.3 per cent. Packard and Willson in 233 cases treated by intracerebral injections of antitoxin found a mortality of 58.7 per cent. Lambert in 52 cases, similarly treated, 87.50 per cent. for the acute cases and 26.66 per cent. for the chronic cases. There are many smaller collections of cases treated by various methods and with a mortality range of from 5 to nearly 100 per cent. Baccelli's method of carbolic acid injections does not appear to have achieved much success outside of Italy.

It appears in general that the earlier the treatment is begun and the larger and more frequent are the doses of antitoxin, the better is the result. Prophylactic injections are almost universally commended, and recorded as most valuable. But it is evident that the mortality figures for the serum treatment of tetanus are too favorable, many unsuccessful cases lacking report.

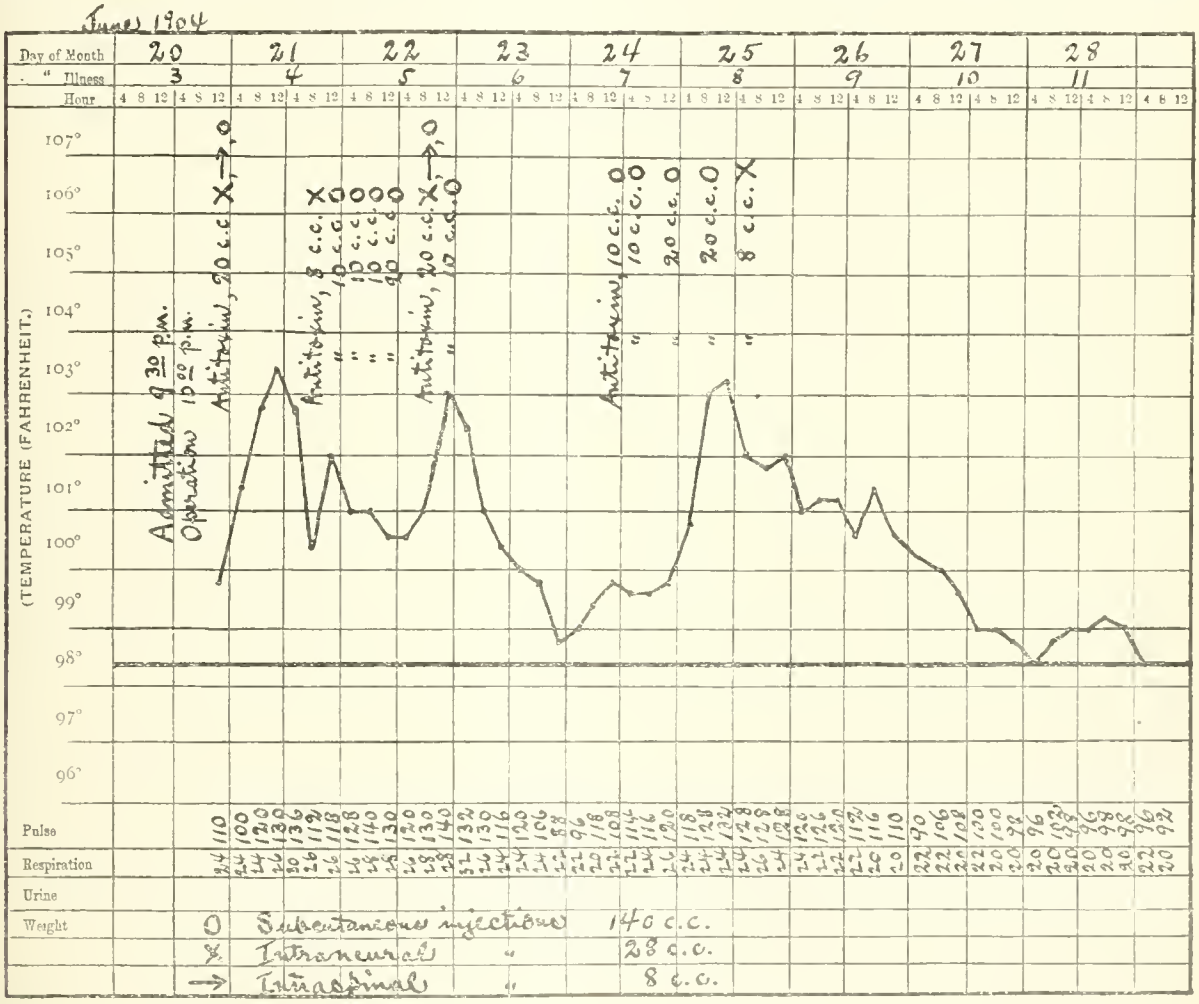
During the past year one of the last links in our chain of knowledge for the successful treatment of tetanus has been welded. How to overcome the toxin in its selective action upon the cells of the central nervous system, when once the symptoms of the disease have appeared, has been the problem. Since Nicolaier in 1884 produced tetanus by injecting garden earth under the skin in mice and rabbits, the sum total of our practical knowledge of this disease has steadily grown. Kitasato isolated the bacillus in 1889. Kitasato and Behring in 1890 showed that animals could be immunized against tetanus. Wassermann and Takaki showed that nearly all the toxin is taken up by the nervous tissue. Roux and Borrell in 1898 experimentally injected antitoxin into

the brains of tetanized guinea pigs. Blumenthal and Jacob in 1898 experimentally injected antitoxin into the subdural spaces in goats. Castromnovo, Bolton and Fisch, Zupnik and others did much experimental work upon the occurrence and distribution of the tetanus toxin in the animal body. Marie and Morax in 1902 and Meyer and Ransom in 1903 experimentally established the fact that tetanus toxin reaches the central nervous system only through the intact axis cylinders of the motor nerves, and moreover through the muscle end plates of these nerves. Furthermore, that it can travel only centripetally along them. Antitoxin follows the same course. Toxin or antitoxin, wherever generated or introduced, is first carried by the circulation to the end plates, or to some anatomical wound of the nerve fibres or trunk before the ascending journey to the central nervous system can begin. To traverse a nerve to its origin in the cord takes several days—the time varying directly as the nerve length.

It is obvious, therefore, why it is, when once symptoms have appeared, that treatment of this severe disease by subcutaneous injections of antitoxin so often fails in the acute cases, since so much time must elapse before the antidote can begin to neutralize the poison.

The exposure, by operative procedure, of the nerves of the part affected, and the injection of antitoxin into their trunks, allows not only a direct entrance for the antitoxin with consequent saving in time, but blocks the path for further toxin absorption by neutralizing that which is ascending. The nearer to the affected cells in the spinal cord the antitoxic serum can be placed, the better. Lumbar puncture (or even higher) should be done, the nerves of the cauda equina should be scratched, and antitoxin injected. Rogers has suggested the applicability of laminectomy to enable one safely and surely to scratch the cord. Meyer and Ransom seem to have been the first to treat the disease by this method, and successfully. Rogers' brilliant work should prove a stimulus to the method in this country. To his two papers (MEDICAL RECORD, May 21 and July 2, 1904) and reports of two cases successfully treated, I am indebted for much information.

The following case of acute tetanus furnishes, I think, very strong additional proof of the superior efficacy of the intraneural and intraspinal injections of the antitoxin in the treatment of this hitherto very fatal disease. This patient was admitted upon the Surgical Division at St. Luke's Hospital to the service of Dr. Robert Abbe, to whom it was referred by Dr. C. G. Kerley. For the privilege of observing the case and administering a number of the injections, as well as for this report, I am indebted to Dr. Abbe. The method, as reported by Rogers, was followed.



E. D., a boy of 5 years, seven days beefore he was taken sick, had stuck a very small sliver of wood beneath the skin on the outer side of the right knee. On Saturday, June 18, he complained in the morning of his jaws feeling stiff, especially at meal time. He could not open his mouth freely, and "ceased to laugh heartily." Was restless that night. The fol-

lowing morning there was quite marked rigidity of jaw and neck muscles, the boy could not take solid food, and complained of pain in the back of the neck and in the back. He walked with difficulty. He was seen by Dr. Terhune, the family physician. The first marked spasm occurred that evening.

Thereafter he was unable to turn himself in bed.

June 20.—All the symptoms increased in severity and spasms occurred frequently in the afternoon and during the ride to the hospital, to which the patient was admitted 9:30 P. M. The boy was of average frame, well nourished. There was moderate continued opisthotonos with head retraction and general muscular rigidity. The muscles of the right side seemed more affected. Slight spasms occurred about every ten minutes and lasted half a minute, but without cyanosis or labored breathing. Severe spasms were provoked by palpating the muscles of the back or neck. There was some photophobia. Trismus prevented a separation of the teeth of more than one-third of an inch. The pupils were equal and normal; the temperature was 99 4-5° F., the pulse 110. There was a very small healed wound on the right knee without local reaction.

The operation was performed at 10 P. M. The anterior crural and sciatic nerves were exposed for 1½ inches and raised on a flat probe. Injections were made with a fine hypodermic needle and well up and down the nerve trunk, the needle being inserted several times in order to slightly wound the filaments, three c.c. antitoxin being injected into each trunk. In order to facilitate reinjection of the nerves and to allow as much absorption of antitoxin as possible, the wounds were left open and lightly packed with sterile gauze strips saturated with antitoxin. Rubber tissue prevented absorption of the serum into the dressings. A lumbar puncture was made between the second and third lumbar vertebræ, and after allowing a small amount of fluid to escape 3 c.c. antitoxin was injected. At the same time an attempt was made to scratch the nerves of the cauda equina. Ten c.c. of serum was then given subcutaneously.

During the night patient had three marked and many slighter spasms. Chloral and potassium bromide given by rectum produced a quieting effect.

June 21.—Convulsive seizures were more frequent and more severe, controlled somewhat by chloral and bromide of potassium and chloroform inhalation. Temperature 103.4°, pulse 120 to 130. The intraneural injections were repeated under chloroform. During the night the spasms decreased.

June 22.—In the afternoon and evening the spasms were more severe again. The intraneural and intraspinal injections were repeated under chloroform.

June 23.—The patient was much weaker, having had several severe spasms during the night. The spasms were more frequent and severe during the day, requiring chloroform inhalation repeatedly.

June 24.—Condition improved; spasms less severe and frequent. This was the first day that diminished rigidity of jaw could be noticed. In the afternoon and evening there was some increase in the frequency and severity of spasms, and one of the most severe type occurred, accompanied by cyanosis and a barely perceptible pulse.

June 25.—There was one severe spasm again in the morning. The intraneural injections were repeated. The boy was able to take nourishment more freely during the day.

June 26.—The patient passed a better night, having had no spasms since 10:30 the previous evening. From the 26th to the 29th slight spasms occurred, but only in the mornings and at about the same time every day (8 to 10 A. M.). Improvement was steady and continuous, and the patient was allowed up on July 9 (the twentieth day after admission). There was no disability and the wounds had healed without suppuration.

The effect of the chloroform given for the injections and for the relief of the more severe spasms seemed decidedly beneficial and absence of spasm would be noted for some time after it had been given. Brandy, 15 to 20 drops every three or four hours, was given for several days by the mouth with the food. Chloral and potassium bromide were used from time to time, with the effect of diminishing somewhat the frequency of the contractions. The little patient was able, as a rule, to take a fair amount of fluid nourishment by mouth—but one day occurring during which practically nothing could be given in that way.

The very small, completely healed, and insignificant scar on the knee was not excised, as its appearance was so entirely healthy and without sign of local disturbance whatever. It is hardly necessary to say that energetic local treatment of existing wounds, even to excision, should always be employed.

The patient received nearly 180 c.c. antitoxin (some was lost in intraneural injection and some used in wound packing). The case of Meyer and Ransom and the two cases of Rogers are the only ones that I have seen reported as treated by this method to the time of writing. That the method is the greatest advance in the treatment of this grave and very fatal disease that has yet appeared and a triumph for surgery, these four cases (two of early development) would seem to show.

A temperature chart of the first eight days is appended and marked with the quantity, time and site of the antitoxin injections. The value of the intraneural and intraspinal injections over the subcutaneous administration is, I think, well shown in the temperature curve and pulse record.

Temporary Idiosyncrasy Against Mercury.—Berliner reports a case in which mercurial inunctions in a pregnant woman were followed by most alarming symptoms. During the sixth month of her pregnancy the patient developed a typical specific angina, accompanied by lesions of the mucous membranes and a macular eruption. The infection could be verified and the woman was given daily inunctions with 3 grams of mercurial ointment. Three days later she developed a severe enteritis, which failed to respond to the usual astringent treatment, and was accompanied by an extreme prostration. The symptoms disappeared within three days after the treatment was discontinued, only to return when it was again instituted, although in lessened dosage. The mercury had finally to be entirely omitted. A full term child was born, which died within five weeks of melæna and syphilitic pemphigus. Six weeks after delivery the inunctions were again started and continued without any evil effects. The author attributes the diarrhœal condition to the swallowing of saliva, which was very profuse. The teeth and gums were also in bad condition.—*Allgemeine medizinische Zentral-Zeitung*, Aug. 6, 1904.

Hemorrhage Before, During, and After Labor.—Julius Rosenberg discusses here the hemorrhages due to a premature detachment of the normally implanted placenta, placenta prævia, and post partum hemorrhage. He draws a vivid picture of sudden, severe hemorrhage during labor. He believes that Graves's disease is a potent etiological factor of accidental hemorrhage, the immediate cause being vasomotor disturbances which are present in this disease. Traumatism, direct or indirect, is named as a cause. Emotion, hydramnios, multiple pregnancy, unusual shortness of the cord, and anatomical abnormalities, may all produce premature separation of the placenta, but the most important factors are syphilis, nephritis, and uterine tumors. In concealed hemorrhage, the prognosis for both mother and child is very grave. In external hemorrhage the mother's chances are better. The mother only should be considered. Delivery should be attempted at once. The uterus must be emptied before the bleeding will stop. If possible, version, forceps, or craniotomy should be performed, but if the cervix remains intact, it should be incised. The supravaginal part, however, must first be dilated. When the placenta is attached to the lower uterine segment, it is called placenta prævia. The writer describes his treatment of hemorrhage in cases of undilated cervix as follows: The vagina is tamponed at once with iodoform or sterilized gauze, whether labor pains are in progress or not. The tamponade must be firm, especially in the fornix vagina. This treatment generally stops the bleeding. If the cervix will admit the finger, the membranes should be ruptured. If the hemorrhage is profuse, and the larger part of the placenta occupies the cervix, combined version is the best treatment. The writer emphatically opposes the forcible extraction of the child through the partly dilated cervix. Postpartum hemorrhage often follows accidental hemorrhage and placenta prævia. Hemorrhage with the placenta still in utero is generally due to undue interference during the third stage. The uterus must be emptied without delay. True postpartum hemorrhage, that is, after expulsion of the placenta, is due to an atonic state of the uterine muscle. Hemorrhage should be combated before delivery. All should be ready for this possible complication. Before treating the condition the source of the bleeding should be determined. Uterine massage is the quickest method in atonic hemorrhage. Intravenous infusion should be saved for desperate cases. After the hemorrhage is arrested, physiological salt solution should be injected into the rectum and under the skin of chest and thighs. For the flagging heart, the writer uses the hypodermic injection of camphor in a 1:9 solution in oil of sweet almonds. Hot cloths upon the chest and precordium have an excellent effect upon the circulation and respiration. Feeding by mouth must be avoided. The writer employs the ice-bag after any intranteurine manipulation. It saves the patient much pain and is a good prophylactic against inflammation.—*The American Journal of Obstetrics.*

Innervation of the Heart and Use of Cardiac Stimulants in Treatment of Shock.—O. O. Witherbee, in discussing the treatment of shock, declares that something is needed which will affect not only the vessels of the splanchnic area, but also those of the entire vascular system, and at the same time exert a direct action on the fibers of the heart. This must act independently of the nerve apparatus, and the manner of its introduction must be such as to admit of the least possible delay. He shows that extracts from the suprarenal gland have met the indications in a larger percentage of cases than has any other therapeutic agent yet used. This drug has a direct action on the heart and blood vessels, as well as on both the central and peripheral vasomotor systems. It is also a respiratory stimulant, and increases general metabolism and body temperature. It is not markedly toxic, and may be safely given far in excess of amounts sufficient to increase blood pressure.—*California State Journal of Medicine.*

Non-Diphtheritic Membranous Anginas.—Louis B. Wilson gives the following groups of microorganisms which have been found constantly associated with the 5 types of pseudomembranous anginas that have been hitherto reported. They are associated with (1) streptococci; (2) diplococcus pneumoniæ; (3) Friedländer's bacillus; (4) the spirillum of Vincent, and (5) blastomycetes. In the last group, besides thrush—due to oïdium albicans, which is at times anginal in character, there is considerable evidence that quite an important group of anginas is associated with the presence of a blastomycetic organism often called "yeast." The writer presents the following summary and conclusions: (1) The non-diphtheritic pseudomembranous anginas may be divided into several groups, each of which is a more or less distinct clinical entity associated with a species of microorganism, either alone or in great preponderance. (2) These non-diphtheritic anginas are important not only because of the necessity of differentiating them from diphtheria, but also because (*a*) they are frequently transmissible, and (*b*) their treatment should vary according to the microorganism present. (3) Our present imperfect knowledge of these anginas should be added to by carefully made and carefully recorded clinical observations in connection with full bacteriological investigations. (4) In order to determine as early as possible the etiological factor in anginas, direct coverslip or direct slide preparations from the membrane (as well as cultures on the ordinary diphtheria media) should be made by the physician on his first visit. These should be dried without heating, then fixed by heat and either stained by the physician or sent to a laboratory with the culture for further examination. This technique should be supplemented whenever possible by cultures on media more suited to the development of non-diphtheria-like microorganisms than is Löffler's blood serum, such, for instance, as broth or agar, both neutral and acid.—*The St. Paul Medical Journal.*

The Piezometer, an Instrument for Measuring Resistances.—Howard A. Kelly describes a new instrument, which he declares is not intended to replace the method of palpation, but to supplement or to confirm the results obtained by it. It is intended to register varying degrees of resistance. By its use a simple, scientific, objective means of demonstrating pressure is substituted for the subjective methods, which depend upon the use of the fingers. The instrument consists of a slender, graduated rod, about 30 cm. long. It is divided into centimeters from the lower end up to a metal cylinder, about 13 mm. in diameter, and 18½ cm. in length. In this the upper part of the rod is enclosed. This cylinder has an opening about 10 cm. long, in which slides an indicator attached to the rod that, when not in use, is held at the lowest point by a spring, where it registers zero. The distance between the zero mark and the upper part of the fenestra is graduated by hundreds up to 2 kilometers. A fenestrated wheel slides on the rod, between the button at its lower end and the cylinder. By means of this instrument one is enabled to estimate varying degrees of resistance, thus ascertaining the amount of pressure necessary to elicit tenderness, while at the same time the instrument registers the depth of the depression made on the skin surface, by means of the wheel. The instrument may be used for several purposes. For outlining an abdominal tumor, by using a given degree of pressure, for example, 800 grams; the depth of the impression made by it, as registered by the wheel, is noted. When pressure is made over a tumor only a slight depression is registered. When the same degree of pressure is made over the soft parts of the abdomen, the rod may sink in as much as 2 cm. or more. The piezometer may be used for estimating the degree of rigidity in the right iliac fossa, in doubtful appendicitis, by comparison between the rigidity of the right and left oblique muscles. Again, it may be used as an algesimeter. It will prove of great value to the teacher of physical diagnosis.—*Bulletin of the Johns Hopkins Hospital.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 15, 1904.

THE SUPPRESSION OF TYPHOID FEVER AT ITS SOURCE.

NEW YORK CITY is passing through its annual visitation of typhoid fever in rather more aggravated form than usual this autumn. The large morbidity and mortality figures for typhoid fever presented in the weekly report of the Health Department have served to direct public attention to the prevalence of the disease, but except that the figures are a little larger than usual, there is nothing peculiar in the present autumnal epidemic. We have it every year—this "vacation typhoid," and it is the penalty we pay for our foolish trust in "the old oaken bucket." We go to the woods and the mountains asking for health and we get disease. This is the chief source of our typhoid fever, the importation of the bacillus in the bodies of its victims, but there is doubtless some brought in with milk and salads. In whatever way it comes, however, it comes from the country, and is never city bred. This is as true of every city as it is of New York, hence if we would do away with typhoid fever we must initiate the work of sanitation in the country. The filtration of the water supply is an excellent safeguard, and expensive as it is, it would well repay every city to install a filtration plant; the boiling of water will undoubtedly kill all the contained microbes—the good with the bad unfortunately—but if this method is to be effectual all the water, that for bathing and dishwashing as well as for drinking, must be treated; but when all this has been done our salads and other vegetables eaten raw may carry infection, and milk cans and bottles may be washed in infected water or the milk may be diluted with it. We are then at the mercy of the country, and we must demand of the country a sanitary reform.

In a well reasoned paper read at the annual meeting of the Connecticut Medical Society in May of this year, Dr. William C. Daggett, of New Haven, insists upon this fact of the rural origin of urban typhoid fever. He shows that in a sense the inhabitants of even the most remote country districts are neighbors of the city dwellers and as such they must not be allowed to maintain a nuisance. There is, he says, an ever increasing likelihood that the water on the farm will in some way reach the city, either directly through the public water supply or indirectly through the medium of milk or vegetables, and the farmer should therefore be held strictly accountable for the sanitary condition of his premises. The *fons et origo mali* is, of course, the country privy, the location and construction of which are, more often than not, faulty, and which is in consequence a potential focus of an epidemic of typhoid fever, either in the immediate neighborhood, or, more probably, in some distant town the water supply of which is drawn from the water shed which this privy pollutes.

In order to bring about a change in these conditions, Dr. Daggett suggests the organization under legislative enactment of a board of State sanitary inspectors, permanent in character, each member to be a competent civil engineer (we think one, at least, should be a sanitarian with medical training), this board to make a detailed sanitary survey of the State with reference to the relative locations of privy vaults and sources of water supply, with power to condemn and relocate wells and privies when necessary, and with instructions to advise the people as to the use of screens and the guarding of compost heaps to check the breeding of flies. The inspectors are to make frequent rounds of their respective districts to see that their recommendations are enforced, and to advise in all matters of a sanitary nature.

We are in hearty accord with the spirit of the above suggestions, and would urge that they be seriously considered by physicians, health officials, and legislators everywhere. The outlay would be large, but the returns would be far greater, and the resultant education of the people would bring about not only a radical diminution in the number of cases of typhoid fever, but also a marked decrease in the prevalence of other diarrhœal diseases which are fostered by unsanitary conditions. The Connecticut State Board of Health has taken the matter up, has had Dr. Daggett's paper printed for general distribution, and will endeavor to have suitable legislation along the lines here suggested enacted during the coming winter.

THE ORIGIN AND FUNCTION OF NEOPLASMS.

DR. MARY A. DIXON JONES, in a recently published article on the origin of fibroid tumors and other pathological formations in the internal organs of generation in women (*Annals of Gynecology and Pediatry*, September, 1904), calls attention to the great importance of considering the pathological conditions of the immediate and neighboring tissues, and the condition of the uterus in which fibroid tumors have developed. Referring to a previous article, published in the MEDICAL RECORD in the year 1903, she reaffirms the statement that, in cases of uterine fibroids she has invariably found the uterine appendages diseased. Again, she has found that when there was disease of the uterine appendages, the condition of the uterus was profoundly abnormal. When the muscle fibers of the uterus become more and more reduced to granular material or to protoplasm, all is ready for the development of small fibroid tumors and the formation of larger and more solid structures. Fibrocystic tumors are formed on the same principles. A myoma, when reduced to primal elements, may form any growth or develop any pathological formation. In the numerous specimens that the writer has examined she has always found that the tissues of fibroid tumors are very much diseased. She quotes the words of Christ: "Verily, verily, I say unto you, except a corn of wheat fall into the ground and die, it abideth alone: But if it die it bringeth forth much fruit." This she calls the "added proof." Physiologically, by the tissues dying, they bring forth much fruit. The

healthy tissues become inflamed, almost suppurating, and die, and then bring forth these new structures. It is by the death of normal tissues, or by their being reduced to their primal elements, that new pathological formations are developed. This is the only way they can develop. The writer likens these changes to the resurrection from the dead, and she points out how the Bible can give us light on many deep physiological problems.

These growths, Dr. Jones maintains, have the function of prolonging human life. For if the tissue elements did not go on to these new formations, they might form pus and sloughs and lead to death. Many dangers are thus prevented by these new growths. The writer explains the etiology of these new formations as follows: First, there is infection, than inflammatory corpuscles, or medullary material in which any new growth may be developed. In this material there exist the life elements for any pathological change. In these diseased tissues new fibroid tissue is forming, and the diseased tissues are being used up, the tumor is increasing in size, and the immediate danger to the patient's life is removed. This same series of changes keeps on, and it is the life-saving structures that are in active operation, whether the results are fibroid tumors, fibrocysts, blood corpuscles, or other formations. These same principles are applicable to the development of cancer. Its development prolongs the patient's life. As the writer tersely expresses it, "all pathological changes are life-saving efforts." She concludes the paper by emphasizing the importance of attention to the simple laws of health. By obeying them she believes that many of these pathological formations might be prevented by preventing the conditions which lead to them.

WOOD ALCOHOL.

The recent occurrence in one small section of this city of between twenty and thirty deaths, believed to be directly traceable to drinking a so-called whiskey made by coloring and flavoring diluted methyl alcohol, calls attention in a forcible manner to this new menace to life and health. Up to within a comparatively recent period cases of poisoning by wood alcohol were among the rarities of medical practice, for so long as the substance was manufactured by the old processes its offensive smell and taste were sufficient to deter even the most hardened drinker from using it to satisfy his craving for alcoholic stimulants. Since the time, however, that "deodorized" wood alcohol has been placed on the market, under various names, the fatalities from its use have gone up by leaps and bounds. Not only may it be used in place of grain alcohol in the manufacture and adulteration of spirituous liquors, but it is also largely and widely used as a menstruum in many toilet preparations and remedies for internal and external use. The reasons for this practice are twofold. First, and that which appeals most forcibly to human nature, is the comparative cheapness of wood alcohol, it being untaxed and costing but 50 cents per gallon, while grain alcohol, taxed, costs at retail $2.60 per gallon. The second reason is the ignorance of many manufacturers as to the deadly nature of methyl alcohol. Indeed, even among members of the medical profession views with regard to the poisonous nature of methyl alcohol are widely divergent, and some who have had no experience in cases of wood alcohol poisoning are openly sceptical concerning its reputed toxic properties. In order, therefore, to decide the question, Dr. Frank Buller of Montreal and Dr. Casey Wood of Chicago undertook in the beginning of 1904 an investigation of the subject, under the auspices of the Section on Ophthalmology of the American Medical Association. An exhaustive paper embodying the results of these investigations is published in a recent issue of the *Journal of the American Medical Association*. The investigators found that about 175 cases of blindness and about 100 deaths during the past seven or eight years could be directly imputed to wood alcohol in the various forms in which it is manufactured. This estimate is a conservative one and only treats of published instances of death and blindness.

Into the question of the manner of poisoning by wood alcohol, there is no space here to enter, but it may be said that all observers agree that the symptoms of such poisoning are unmistakable, and that the eye is the organ especially attacked.

Drs. Buller and Wood consider that the investigations undertaken by them confirm the suspicions entertained by many physicians that the fumes of wood alcohol, under certain favorable conditions, are a dangerous menace to eyesight, and they moreover believe that the consensus of opinion is opposed to the statement of the makers of the various forms of "deodorized" wood alcohol that its external use in liniments, alcohol "rubs," in baths, in cosmetics, hair tonics, perfumes, etc., is always devoid of danger to the eyesight.

The practice of substituting wood for grain alcohol in the manufacture of medicinal preparations would appear to be a most insidious and pernicious means of poisoning, and the sale not only of methyl whiskey but also of internal remedies and toilet preparations manufactured or adulterated with wood alcohol should be restricted by law. In fact, there is every reason why the proposition of Drs. Buller and Wood should be adopted that methyl alcohol in any of its forms should be treated as a poison and subject to the laws of the various states restricting and regulating the sale of poisons.

PHYSICIANS FOR THE CANAL ZONE—A WARNING.

OUR Washington correspondent writes that the Canal Commissioners have decided to employ a large number of recent medical graduates as internes in the hospitals along the route of the canal. The salary has been fixed at $50 per month with living expenses, and the term of service will be two years—doubtless with the privilege of renewal. There will, of course, be no difficulty in securing the required number of well qualified men on these terms, poor as they are—indeed, we understand there are already over five hundred applications on file, but any graduate in medicine who contemplates applying for appointment in the service should seriously consider what such a step means. The love of adventure is strong in the young, and the pull of the tropics on the native of the north is powerful; but there will be little of adventure for the house officer in a lonely hospital in the centre of the Isthmus, and a tropical climate, after its first temporary stimulating effect, cripples the will and weakens the body of the unacclimated northerner. The great tropical plagues, malaria and dysentery, are theoretically avoidable, but practically every one is

in constant danger where they prevail, and other diseases there are which incapacitate if they do not always kill. The true physician, like any other true man, would never shrink from his duty through fear of disease or death, but no duty calls the civilian physician to the Isthmus; no young man should delude himself with the thought that his country needs his services on the Canal Zone. He will be hired to do a certain work, just as the canal laborers will be hired to dig, and if he falls out by the way or comes home invalided and with a shattered constitution, his country will give no further thought to him; his pay will stop and he can support himself as best he may or live on his relatives or the county. The salary of fifty dollars a month will not go far at Panama, and the young man who thinks he will be able to save enough from it in two years to give him a good start in practice after his return home will be disappointed.

We have purposely exposed the dark side of this picture, not with a view of discouraging any young man, free from home ties, who can live his life as he will, from seeking a medical appointment in the Canal Zone, but only that he may do so with his eyes open. And that life there will not be without its attractive side we are free to admit. The climate of the Isthmus, in spite of what those who know only Colon may say, is in general not bad; the heat is not intolerable, and with care and good luck one may keep his health, though the vigor infused by winter cold will fail. The work will probably not be very onerous, and though the future will not be provided for, the daily needs of existence will be met sufficiently. Then for one who loves his science, the rich opportunity to study tropical diseases, which life in a canal hospital will provide, will go far to compensate for many drawbacks. We would simply warn those who are tempted to go to the Isthmus to remember that the actualities of life there will be very different from what the imagination pictures them, and that there is no patriotic call to which they must respond. No individual's services are needed there, for there will be more applications than there are places to fill, and if one goes let him go with a knowledge of what he is doing, undeceived by the glamor of adventure and of the *dolce far niente* of the tropics of the poet and the dreamer.

Fighting Tuberculosis in Prisons.

As is well known, and as also might be expected, the inmates of prisons are frequently the victims of tuberculosis. It stands to reason that the environment of prisons should be especially favorable to the development of this disease. Dr. Julius Ransom, writing on this subject, states that the mortality from tuberculosis is variously estimated by the best authorities at from 40 to 55 per cent. of all the deaths occurring in the prisons of the world. There are many isolated cases in which the mortality from this cause has reached a much higher percentage, and at one time in the State of New York it reached 75 per cent. of the total prison deaths. One of the chief predisposing causes of tuberculosis is, as Dr. Ransom points out, an unstable nervous system, and in prison life nearly all the factors exist calculated to undermine the nervous system and render it unstable. Age is also a predisposing cause which plays an important part in the development of tuberculosis in prison. Prisoners average about 30 years of age, a period which is especially favorable to infection by the tubercle bacillus.

Dr. Ransom sketches the history of the movement instituted against tuberculosis in Clinton prison, at Dannemora, N. Y. When he first began service there he found that tuberculosis was prevalent and that the means of fighting it were defective in every way. Owing to continued agitation, the legislature appropriated the sum of $2,500 for the purpose of constructing a ward for the treatment of tuberculous patients. At the present time there is in Clinton prison a total capacity of 54 beds for tuberculous inmates. The treatment in all respects is conducted on the lines of modern methods, physical and dietetic, with the administration of some medicine and the use of ultra-violet rays. The only drawback is that, owing to prison conditions, the tuberculous patient cannot obtain the amount of open air that his condition requires, but, notwithstanding this, the men improve in an astonishing manner.

Dr. Ransom concludes his interesting account by pleading for a further extension of the system inaugurated so successfully at Clinton prison, and urging also upon the legislature the need of constructing prisons of a less mediæval type. The danger of the prisoners spreading infection when liberated must count for something and it is one against which the public at large has a right to expect that the State will guard. Hence the care of consumptives in prison is a step in the right direction, if only to safeguard to some extent the health of the general community. The day when the criminal was treated like a dangerous animal has passed, never to return, and the care of his health is in line with the development of the humane system of reforming by intelligent means rather than deterring from crime by cruelty and brutality.

The Postponement of Medical Union in New York State.

We noted last July the attempt of certain members of the Onondaga County Medical Association to defeat the plan of union of the two State medical organizations by raising the plea of illegality in Justice Fitzgerald's court in this borough. This plea was unfortunately sustained, and the hopes of a lasting peace in the medical ranks in New York State must therefore be abandoned for the present. The point raised was that, inasmuch as the by-laws of the State Association contained no provision for the manner of giving notice of meetings, it was necessary to fall back upon the common-law rule. According to this, when a meeting of any organization is to be held for the passage of resolutions affecting privileges or property rights acquired by membership in such organization, the notice of the meeting must be served upon each member personally (not through the mail). Of course no such notice of the special meeting of March 21, at which the plan of union of the two State societies was endorsed, was given, hence the court has ruled that that meeting was held illegally and that the resolutions then adopted were of no force and the action taken was binding upon none of the members. We understand that notice of a proposed revision of the by-laws, providing for a simple manner of calling meetings, will be introduced at the coming session of the State Association in this city; but such notice must stand over one year before being acted upon, and if we read the signs aright there will be considerable opposition to any revision of the by-laws of the Association in October, 1905. Those who opposed union believe they have not postponed it only, but have made it impossible for all time. We trust they will be disappointed.

News of the Week.

Dr. Brooks H. Wells of this city has been appointed attending gynecologist to St. Vincent's Hospital.

A Commers in Honor of Visiting Scientists.—On Saturday evening, October 8, the Society of Old German University Students in America gave a Commers at the Arion Club in honor of the German delegates to the International Congress of Arts and Science recently held at St. Louis. Dr. Carl Beck, president of the society, presided, and was assisted by the vice-presidents, Drs. Cæsar A. von Ramdohr, William C. Alpers, W. Pfizer, and William Hallock Park, who sat each at the head of one of the tables. Among the guests were Lamprecht, the historian of the University of Leipsic; Sombart, the political economist of Breslau; Dessoir, the chemist from the University of Berlin; Laquer, professor of medicine at Wiesbaden; Quidde, of Munich; Sonnenschein, who went from Germany to London to teach chemistry; T. Clifford Allbutt, of Cambridge; Furtwengler, professor of art and history in Munich; Rein, of the faculty of philosophy at Jena; Liebreich, professor of therapeutics at the University of Berlin; Richter, of Baden, and Ettore Pai, of the University of Milan.

Drug Counterfeiters Arrested.—The police of this city arrested last week a gang of men charged with counterfeiting certain patent medicines and proprietary coal-tar analgesics and hypnotics. Millions of pills, put up in imitation of a popular patent medicine, were seized, and also vast quantities of spurious coal-tar products; among the latter were some tried remedies in constant employment in legitimate medicine. Samples of the "fake" stuff were obtained, it is alleged, at over 1,500 drug stores in this city and vicinity. These arrests are the result of a long and patient investigation extending over nearly nine years. The authorities say that they have now in their possession sufficient evidence to show exactly how the swindlers worked. There are charges enough against several men to give them long terms of imprisonment if convictions follow the well-planned arrests.

Wholesale Poisoning by Wood Alcohol.—In a limited area on the West Side of this city upwards of thirty men and women have died within the past three weeks, it is believed of poisoning by amyl alcohol. Most of them were known to have drank heavily of whiskey purchased at a certain saloon, one of the barkeepers of which was also one of the victims. It is supposed that the whiskey was doctored stuff, the basis of which was wood alcohol, flavored and colored with various chemicals. The police, the health department, and the coroner are all investigating the cases, and analyses are being made of the gastric contents of the dead and of the liquor found in bottles in the rooms formerly occupied by them.

In Memory of Dr. Lazear.—A tablet in memory of Dr. Jesse William Lazear, who lost his life during the yellow fever experiments conducted by Major Walter Reed in Cuba, has been placed in the new surgical building of Johns Hopkins University. At the unveiling of the tablet on October 5 addresses were made by Prof. T. Clifford Allbutt, of Cambridge, England, Dr. Lewis A. Stimson, of New York, and Dr. James Carroll, Assistant Surgeon, U. S. A., who was one of Dr. Lazear's associates on the Commission, and who himself suffered from the fever, narrowly escaping the fate of his colleague.

A Reception to Sir T. Lauder Brunton of London was given on October 3 by the Philadelphia Medical Club. In a brief address the distinguished guest expressed envy of the superabundance of energy of the American people and appreciation of their great opportunities for learning. He predicted that instead of physicians going from the United States to England and other European countries to study the most advanced thought in medicine, the tide shortly would turn in other directions, and physicians from France, Germany, England and other Old World countries would come to America to study and to do research work that they were unable to do in their own countries. Preceding the reception, a dinner was given to the guest by the president of the club, Dr. E. E. Montgomery.

New Professors at Columbia.—A reception was given to the newly-appointed professors in Columbia University on Saturday, October 8, in Earl Hall. Among the new professors are the following in the Medical Department: Gorham Bacon, Professor of Otology; Joseph A. Blake, Professor of Surgery; George E. Brewer, Professor of Clinical Surgery; James R. Hayden, Professor of Genito-urinary Diseases; Arnold Knapp, Professor of Ophthalmology; Samuel W. Lambert, Professor of Applied Therapeutics; Harry McMahon Painter, Professor of Clinical Obstetrics; Frederick Peterson, Clinical Professor of Psychiatry; William Kelly Simpson, Professor of Laryngology; John S. Thacher, Professor of Clinical Medicine; Frederick R. Bailey, Adjunct Professor of Normal Histology; Eugene Hodenpyl, Adjunct Professor of Pathological Anatomy; Russell Burton-Opitz, Adjunct Professor of Physiology; Francis Carter Wood, Adjunct Professor of Clinical Pathology.

Camps for the Tubereulous.—A circular letter was recently issued by the Illinois State Medical Society, the Illinois State Homœopathic Society, and the Illinois State Eclectic Medical Society, jointly, setting forth the purposes of a crusade against tuberculosis and asking citizens to join in the work of promoting the movement. The circular states that a large proportion of lives can be preserved by the early recognition of the disease, and the prompt placing of the sufferers under proper hygienic conditions in tuberculosis camps within the borders of Illinois. Such camps, it is argued, should be established and maintained by the State for the benefit, primarily, of the poor who are afflicted with the disease, and, secondarily, for the protection of the community against its spread. Similar camps are in successful operation in Pennsylvania and in some other States of this country. The camp at Ottawa, Illinois, under the administration of Dr. J. W. Pettit, of that city, is run on as nearly a self-supporting basis as possible, all medical services being gratuitous.

New Open-Air Hospital for Tuberculosis.—Philanthropic Cincinnatians will establish a free hospital for the open-air treatment of consumption on October 15. The hospital, which will be located back of Price Hill, will start with twelve cottage tents, in which the patients will live winter and summer. Dr. Oswald Katz will be the resident physician.

Cause and Prevention of Consumption.—Under this title, the Illinois State Board of Health has issued a third revised edition of its pamphlet, the first edition of which was published in July. Illinois is recommended as a suitable place for the treatment of consumption, and attention is directed to climatic conditions, elevation, and soil, which are equally as good as, and in some instances superior to, those found at the tuberculosis sanatoria of Massachusetts, New York, and Pennsylvania.

The Water Supply of New York.—Although at present there is no contamination of the water supply of Manhattan and The Bronx with typhoid bacilli, the unusual prevalence of the disease has led to the taking of special precautions to insure the purity of the water. Along the Croton watershed, all the way from Yorktown down past Amawalk Lake to the big Croton dam, a distance of seven miles, gangs of men are busy cutting down the trees and underbrush, which, as soon as they are dried, will be burned. The Water Commissioners are investigating the sewerage system at Mount Kisco, where, it is reported, there has been considerable typhoid fever. If it is ascertained that there is fever in the town and the sewers connect in any way with the watershed through Branch Brook, the Commissioners will appeal to the State Board of Health to prevent the contamination.

An Amendment to the Smoke Ordinance.—A Brooklyn Supreme Court Justice recently decided that the provision of the Sanitary Code making it a misdemeanor to allow smoke to issue from any building, as the code did, was ridiculous and inoperative, as it was practically impossible to build a fire without having some smoke. To meet this criticism, the Board of Health has amended the code which now makes it unlawful to permit smoke to issue from any building "to the detriment or annoyance of any persons not being therein or thereupon," or to permit the smoke "to enter any other building or to pollute the air in any street or thoroughfare within the city limits."

Medical Society of the State of Pennsylvania.—At the fifty-fourth annual meeting of this society, held September 27-29, at Pittsburg, under the presidency of Dr. William B. Ulrich of Chester, the following officers were elected: *President,* Dr. Adolph Koenig of Pittsburg; *Vice-presidents,* Dr. E. V. Swing of Coatesville, W. S. Stewart of Wilkesbarre, J. M. Corson of Chatham Run, and J. B. Ewing of Uniontown; *Secretary,* Dr. Cyrus Lee Stevens of Athens; *Assistant Secretary,* Dr. Theodore B. Appel of Lancaster; *Treasurer,* Dr. G. W. Wagoner of Johnstown. The secretary, Dr. C. L. Stevens of Athens, was appointed editor and publisher of the *Pennsylvania Medical Journal,* the official organ of the society. The next annual meeting will be held at Scranton.

The Pneumonia Commission.—The following is the constitution of the commission called by the New York City Board of Health to study, and if possible determine, the nature of pneumonia and the causes of its recent increase in this city. All of the members have accepted the invitation of the Health Commissioner to meet here. The commission will include Dr. Frank Billings of Chicago, Dr. Theobald Smith of Harvard, Dr. J. H. Muzzer of Philadelphia, Drs. William Osler and William H. Welsh of the Johns Hopkins University, and Drs. E. G. Janeway, T. Mitchell Prudden, and Emmett Holt of New York City.

Koch in Paris.—It is stated in *The Herald* that Professor Koch was warmly welcomed at the Pasteur Institue on Tuesday of last week. Professor Metchnikoff made a cordial speech, to which Koch replied in his native tongue. The scientists present included Drs. Nicole, Cesredka, Borrel (discoverer of a cancer serum which is now being tested), Chamberland, and Mesnil.

Fraud Order Against the Edison Vitalizer.—An order has been issued by the Post Office Department denying the use of the mails to the Thomas A. Edison, Jr., Chemical Company, on the ground that the company is attempting a fraud on the public in the sale of a "magno-electric vitalizer," which the concern claims has remarkable tonic, reconstructive, and bactericidal powers.

Proposed New Hospital in Covington, Ky.—The committees of the Covington General Council met October 7 and received a proposition from the local physicians for the erection of a hospital. Dr. Frank Eckman said the physicians would erect a modern hospital in the city if the latter would guarantee a certain amount annually, equivalent to the present cost of maintaining the city's indigent. He was requested to submit a written proposition to the Health Committee.

Physician Sues Physician for Fee.—Dr. M. P. Morrell, of St. Louis, has entered a second suit against Dr. J. J. Lawrence to recover for professional services rendered the son of the latter. The amount demanded is $25,000, in addition to $16,000 sued for in a former action still pending. The complainant asserts that for several years prior to the boy's death he was the medical adviser and physician of Dr. Lawrence's son. He further asserts that he sacrificed his city practice and home life to treat the boy in Europe.

The Legality of Christian Science as a method of the treatment of disease has been upheld by the Supreme Court of New Hampshire. A woman sued a "healer" to recover damages for injuries alleged to have resulted from his treatment. The court held that the practice of Christian Science was legal and that patients who resorted to such treatment could not recover any damages in case the practitioner used the accepted Christian Science methods of treatment.

A Tuberculosis Congress met last week in St. Louis. A number of papers were presented, one by Dr. Otto v. Schroen, of Naples, in which it was maintained that pulmonary tuberculosis is an incurable disease. Dr. J. L. Jacobson suggested that a prize be offered to the physician who reports the largest number of cases of tuberculosis in a community. He urged the need of keeping statistics of the number and the condition of the tuberculous patients in a community, and said that one of the best ways to secure these statistics was to offer a prize for the return of information. He also urged the passage of a law making the notification of cases of tuberculosis compulsory.

The Cancer Hospital for Philadelphia.—Application has been made at Philadelphia for a charter for the American Oncologic Hospital, for the treatment of cancer. Two sites for the new hospital are in view, to be bought or rented as soon as the charter has been granted. Among the incorporators are Drs. J. Solis-Cohen, Addinell Hewson, Boardman Reed, G. Betton Massey, B. K. Wilbur, Howard R. Swayne, and C. M. Desvernine.

Spencer Morris Prize.—By the terms of the will of the late Dr. Spencer Morris, a graduate of the class of 1872, the trustees of the University of Pennsylvania have received a sum slightly in excess of $10,000, to be invested and the income to be awarded each year to the medical student in the graduating class who shall pass the best examination for the degree of Doctor of Medicine. It will be known as the Dr. Spencer Morris Prize. It is expected that the income will be about $400 annually.

St. Luke's Hospital, Utica, N. Y., is to have a new building on a new and better site, the gift of Mr. and Mrs. Frederick T. Proctor of Utica. The new building, which is now nearing completion, will have room for eighty beds, and is a fireproof structure of brick, stone, and steel, of the most approved

modern type. The entire expense of the building and furnishing is borne by this one family, and the structure completed is to be turned over to the present Board of Trustees of St. Luke's Home and Hospital.

Dr. William H. Pritchard, former house surgeon at the Cincinnati Hospital, now identified with the Ohio Hospital for Epileptics at Gallipolis, was elected President of the Association of Assistant Physicians of Ohio State Hospitals at the annual convention of the society recently in session at Columbus.

Congress of German Naturalists and Physicians.—The next annual meeting of this congress will be held at Meran, Austria, under the presidency of Professor v. Winckel.

Vital Statistics of Ohio.—There were 64,916 births and 41,376 deaths reported in Ohio last year, and it is believed by the health department that there were many births not reported. The marriages occurring in the State numbered 43,668. Of the deaths 3,237 were caused by tuberculosis and 1,954 by cancer.

Dr. Charles W. Dabney, the new president of the University of Cincinnati, was introduced to the students of that institution on October 5 by Major F. J. Jones, chairman of the University Board. He will be inaugurated November 16.

Dr. Johannes Orth, Professor of Pathological Anatomy and Dean of the University of Berlin, was entertained at a dinner at the Yale Club in this city on October 3, by a number of his former pupils and others.

Smallpox in Illinois.—A mass meeting was held in Bellevue, Illinois, September 28, at which a committee was appointed to secure a location for the erection of an isolation hospital. It is said that there are about ninety cases of smallpox reported to the health authorities.

Bequest to the Hartford Hospital.—According to the will of Miss Mary A. Terry, of Hartford, Conn., who died recently in Venice, the Hartford Hospital will receive the bulk of the estate, amounting to about $300,000. The American College in Beirut, Syria, receives $15,000.

Russian Convalescent Hospital at Cannes.—The Grand Duke Michael recently inaugurated at Cannes a convalescent home for wounded Russian officers. The villa is the gift of Baron de Silvansky, and the cost of furnishing has been defrayed by the Grand Duke Michael, the Grand Duchess Anastasia of Mecklenburg-Schwerin, and Countess Torby.

International Dermatological Congress.—The next meeting of the International Dermatological Association will be held in New York City under the presidency of Dr. J. C. White, of Boston.

New Cincinnati Hospital.—The plans of the new hospital as they now stand provide for thirty-five separate and distinct buildings, all as fireproof as possible, as follows: Administration, three stories; ambulance court, one story; outdoor clinic, two stories; nurses' home, four stories; surgical, one white female, two white male, one colored female and one colored male, two stories; medical, two white female, one white male, one colored female and one colored male, two stories; dermatological, one male, one female, one story each; dermatological for diseased prostitutes, three stories; strong ward, two stories; neurological, three stories; measles, two stories; diphtheria, two stories; scarlet fever, two stories; two children's, two stories; aural and laryngological, two stories; ophthalmic, two stories; gynecological, two stories; operating, two stories; gymnasium, one story; bath, one story; morgue and chapel, two stories; power, two stories; laundry, one story; kitchen, two stories; disinfecting, one story; stable, two stories. Under this plan the sexes are kept separate and to an extent colored and white people are also separated.

Obituary Notes.—Dr. Charles Darwin Sprague, of Peekskill, N. Y., died of Bright's disease on October 7. He was born in Cuba, N. Y., about fifty-two years ago, and was graduated from the medical department of Buffalo University, although he never practised his profession. He lived for a time in New York City, but settled in Peekskill in 1887. He was Park Commissioner and was an amateur photographer of renown.

Dr. Edward J. Belt, of Springfield, Mass., killed himself on October 8, while suffering from delirium. He was born in South Boston, his father being a prominent physician there, and was graduated from the Harvard Medical School. He practised first in Fitchburg, Mass., then in Enfield, N. H., and finally settled in Springfield about two years ago.

Acute Articular Rheumatism.—Burwinkel, in discussing the present day knowledge of this disease, says that the weight of evidence seems to favor the idea that acute articular rheumatism is a disease of the blood, in which the red cells are destroyed in large numbers and the fibrin content of the blood increased. As a result of this marked viscosity of the blood, hyperæmia and thrombosis in the capillaries of regions poorly supplied with vessels are likely to occur, with subsequent exudation. Statistics supplied by various authors, Burwinkel contends, show that the introduction of the salicylates cannot be viewed as a progressive step in the therapy of this disease, for not only are they accompanied by unpleasant after-effects, but there seems to have been an actual increase in the number of cases with cardiac complications. The author's method of treatment comprises complete rest in bed until one week after absolute defervescence. The diet includes plenty of water, fruit, oatmeal soups, zwieback, milk, rice, and spinach, but no meat or meat soups. Three or four times daily he gives the juice of one lemon, together with a teaspoonful of bicarbonate of sodium. Mild hydrotherapeutic measures are recommended. Thorough evacuations of the bowels are necessary. Great value is attached to bleeding, which may be done two or three times during the onset of the disease to the extent of 150 to 300 cubic centimeters (five to ten ounces).—*Deutsche Medicinal Zeitung.*

A Case of Cancer of the Mamma Cured by Means of Roentgen Rays.—E. Schiff reports this case with diagnosis of inoperable cancer en cuirasse of the left mamma with lenticular metastases of the cutis. The left thorax was invaded by a tumor with large basis and of very solid consistence. The tumor extended from the left sternal margin to the axillary cavity, where it reached the glands and formed a hard bunch. The surface was ulcerated and exuded fetid matter. The lower edge showed 10 or 12 small tumors, slightly bleeding. On the patient's back were 5 similar nodules. Beneath the bunch in the axilla there was a crateriform cavity large enough to admit a pigeon egg. The edges were gangrenous. Both supra and infraclavicular glands were hard and resistant. After the third sitting the pain decreased considerably, and the purulent secretion diminished. After five months' treatment the writer noticed that excepting some superficial excoriated parts, a flat scar crossed by some enlarged capillary vessels had taken the place of the former tumor. The cutaneous metastases had disappeared and the groups of soft glands in the supra- and infraclavicular regions had greatly decreased and were soft. The general state of the patient had very much improved. The writer then gives a description of the histological appearance of the tissues, showing that the new growth had almost disappeared at the time of examination.—*Bulletin of The Johns Hopkins Hospital.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OYSTERS AND TYPHOID—FORMIC ALDEHYDE AS A PRESERVATIVE—CORONER TROUTBECK AGAIN—COWELL'S LIFE AND LETTERS—X-RAY JOURNAL—SIR W. MACGREGOR—ITEMS—OBITUARY NOTES.

LONDON, September 23, 1904.

THE subject of oysters conveying typhoid fever is brought before the public again by the appearance this week of the Report of the Local Government Board for 1902-3. Other things are also dealt with in more or less detail, such as vaccination, smallpox, cholera, plague, and various scientific investigations. The sudden outbreak of typhoid in the autumn of 1902 at Winchester and Southampton was investigated for the Board by Dr. Bulstrode, whose exhaustive report is now presented. In both Southampton and Winchester, the mayoral banquets (November, 1902) were followed by illness of some of the guests, some of whom had hardly left the guest chamber before feeling ill. Many others fell sick within three or four days with gastromtestmal disturbances, from which, however, they shortly recovered. But two or three weeks later others developed definite typhoid fever, some of the cases proving fatal. Dr. Bulstrode traced both these outbreaks to oysters, which were served at both banquets, and on further investigation found that the bivalves in question had been furnished to both festivals from a single source, certain "oyster ponds" at Emsworth, which were extremely liable to contamination with Emsworth sewage. At the very time the oysters for the festivals were deposited in the "ponds" these sewers, which were discharging in their neighborhood, were contaminated by the dejecta of typhoid fever patients. Dr. Bulstrode concludes that it is impossible to consider these outbreaks, along with similar data which from time to time come to the notice of the Medical Department, without being impressed with the need that control of the interrelations of the various procedures of shellfish culture and sewage disposal should be without delay vested in competent authority.

Two dealers were fined £5 each and costs on Tuesday for selling milk to which formic aldehyde had been added. Contradictory evidence was given as to the effects of the preservative. The public analyst for Chelsea (Mr. Rideal) said he was the first to experiment with formalin in this country in 1894, and since his paper appeared it had been generally used. He had never known it to be injurious; he had given it to his own children, to kittens and other animals. There was not a tittle of evidence to show that 1 part in 100.000 was injurious even to an infant. He had experimented with fish. A gold-fish throve well in water containing 1 in 40,000, and 1 in 5,000 did not affect the heart of a frog. Dr. Harris, the M.O.H., gave evidence that after taking a pint of milk containing 1 in 100,000 a day for ten days he felt a considerable amount of nausea and discomfort. He thought it must be injurious to young and delicate children. Dr. Toogood, superintendent of Lewisham Infirmary, said formalin was an irritant poison. He could tolerate in dilution of 1 in 5,000; stronger than that it made him sick. He had no doubt that even a solution of 1 in 100.000 delayed digestion if taken for any period.

The fines inflicted in these cases will tend to restrict the use of formic aldehyde, though it may be doubted whether other preservatives will be better. We were told at first that boracic acid was not injurious, but later investigations threw doubt on the subject, and Dr. Harrington (*Am. J. Med. Sci.*) this month makes statements which may well make us hesitate to admit its alleged innocuity.

Mr. Coroner Troutbeck does not seem inclined to adopt a conciliatory course towards the profession. I told you formerly how his conduct led up to a protest. At an inquest on Wednesday he again exhibited himself in a hostile attitude. The deceased had collapsed when at work and was taken to St. Thomas' Hospital, where it was found life was extinct. Dr. Freyberger was again called by the coroner, and said the man died of heart failure while suffering from chronic heart disease. The foreman of the jury wanted to know why the doctor who saw him at the hospital was not called instead of Dr. Freyberger. The coroner said because Dr. Freyberger was the pathologist selected by the County Council to assist at inquests in special cases. But the foreman was not satisfied, said he had seen the controversy about it in the papers, and thought the expense not necessary. Mr. Troutbeck retorted: "You must be inclined to believe foolish things. It is the duty of the coroner to elicit the cause of death, and I do not choose to accept in a case like this the evidence of perhaps an extremely inexperienced house surgeon who has just qualified. And these newspaper controversies, which are carried on by interested parties who are endeavoring to preserve the payment of fees, which I do not think ought to be paid, will not affect the question at all."

But Mr. Coroner Troutbeck was apparently more concerned to flout the profession than to enlighten the jury. Otherwise he might have told them that he had supreme confidence in Dr. Freyberger and was quite willing for his fees to be paid and could recommend him, as he was his own brother-in-law.

In another inquest some time since Dr. Freyberger certainly professed a degree of pathological acumen which I think few would lay claim to. It was a case of a person who died a very short time after displaying symptoms which induced her doctor to suspect insanity was threatening. The patient was watched for a few days, but died of acute pneumonia before any steps could be taken as to certifying or removal to an asylum. Under these circumstances Dr. Freyberger performed the post-mortem for the coroner and testified that the patient had been insane for three and one-half years. After that can you wonder that his brother-in-law has the utmost faith in his pathological knowledge?

Mr. George Cowell, F.R.C.S., has published the "Life and Letters" of his eminent cousin, Edward Byles Cowell, the great orientalist, who went to India as a professor at Calcutta in order to give himself to his favorite studies, and there produced his editions of the Vedic Upanishads and the Yajur Veda. There, too, he mastered the modern Indian languages, as well as Arabic and Persian. No language seemed to come amiss to him, and he became perhaps the greatest master in Europe of Hindu philosophy. Failing health compelled him to return, and Cambridge University elected him Professor of Sanscrit on the foundation of that chair, which he held for some 35 years. His translations from Sanscrit and Persian have obtained a high place, and his biography will interest all admirers of Oriental literature.

The first number of the *Journal of the Röntgen Society* has made its appearance and is illustrated with a portrait of Prof. Silvanus Thompson, a past president. It is intended to give other portraits in the new journal, which is to be issued every other month.

Sir William MacGregor, M.D., late Governor of Lagos, has been entertained by the Liverpool Chamber of Commerce at a dinner when nearly £1,000 was subscribed to be handed to the Liverpool School of Tropical Medicine in the name of and as a memento to Sir William MacGregor. Liverpool may well be proud of her work. Sir William sailed on Saturday for Newfoundland, to which he has been appointed Governor.

The London fever returns last Saturday showed 1,901 cases of scarlet fever, 816 of diphtheria, 185 of typhoid, one of typhus, and 5 of smallpox. In a report of the London County Council, just issued, it is stated that no case of rabies has occurred in London since 1898.

Dr. Edmund Carver, F.R.C.S., etc., Consulting Surgeon to Addenbrooke's Hospital, Cambridge, died on the 14th, aged 80. He was a graduate in Arts and Medicine of Cambridge, at one time president of the Medical Society, and held various other honorable positions.

Lieutenant-Colonel J. H. Beath, M.D., C.B., whose death has occurred in his 70th year, served through the Indian mutiny and was present at Lucknow. He subsequently served in China and Egypt, was mentioned in despatches and decorated by the Khedive and received the C.B.

Mr. S. J. Hutchinson, L.D.S., M.R.C.S., President of the Dental Association, Consulting Dental Surgeon to University College Hospital and to the Royal Dental Hospital, died on the 15th inst., aged 58 years. He has long held a prominent position among our leading dentists, both as a practitioner and a teacher of dental surgery and pathology. He was author of various contributions to the Odontological and Dental associations.

Dr. C. W. Izod, who practised for more than 50 years at Esher and attended several members of the ex-Royal family of France during their residence at Claremont, died on the 16th inst. On the occasion of his jubilee he was presented with a testimonial through the Duchess of Albany, another of his patients, who was present at his funeral.

Dr. H. A. Benham, Superintendent of Stapleton Asylum, died of heart failure on the 14th inst., aged 50. He was lecturer on Mental Diseases at Bristol University College and greatly esteemed by his brethren.

Knock-out Drops of Picrotoxin.—Dr. Casel, writing in the *St. Paul Medical Journal*, reports several cases of "doping" by means of extract of cocculus indicus, called by the criminals who use it for this purpose "extract of hazelnuts." The primary effect of a moderate dose is a profound narcosis, larger doses producing convulsions, followed by paralysis and death. It is important to note, says *The Therapeutic Gazette*, that when picrotoxin is taken with alcohol the loss of power in the voluntary muscles is very much greater than it is in ordinary cases of drunkenness.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Oct. 6, 1904.

Pericemental Abscess.—D. D. Smith presents a most interesting paper on this subject. He cites the history of a case, in which although it was evident that the troublesome tooth was associated with an abscess, the most persistent efforts to relieve it by treatment through the root were absolutely without results. The tooth was extracted at the end of 4 weeks, and lodged in an irregular depression at the root, formed by a slight, sharp bend, about a quarter of an inch from the apex, was a glandular fibrous tumor of the size of an ordinary pea, covered with globules of pus. The base of this growth was relatively large and strongly attached to the pericemental membrane. It had no communication whatever with the pulp and canals. The pericemental abscess is caused by an irritant on the outer surface of the pericemental membrane. In acute cases, the first symptom is pain. This is not severe, but is continuous, and is located by the patient in the offending tooth. The patient always suffers from nervous apprehension in regard to the tooth. There are no marked inflammatory symptoms in the alveolar and gum tissue. The tooth gradually loosens, this symptom becoming more marked as the case progresses. In the chronic form, the escaping pus is discharged at the edge of the alveolus, between the alveolus and the gum, commonly between root bifurcations. The condition is wholly unlike the fistulous opening of an alveolar abscess. The writer declares that the nucleus of this inflammation and the resultant tumoric abscess is in touch with some stagnant, septic irritant upon the tooth or teeth, the external surface of the pericemental membrane alone being involved. The cavities and pits in the alveolus become cesspools of pus, prolific foci of infection. The writer believes that the nerve centers are the special points attacked by the pyæmic toxins from this abscess. He states that pericemental abscess, with its pyogenic infection and enfeebling effects, has doubtless been a predisposing factor in many cases of pneumonia. Pericemental abscess is virulently infectious and is incurable, except through the loss of the tooth.

New York Medical Journal, Oct. 8, 1904.

Observations on Carbolic-Acid Poisoning.—C. V. Burke has treated twelve cases of this nature. Two recovered and ten died. One patient was a hysterical girl, who had probably taken very little poison. She recovered, as did also a second patient, who had taken about an ounce with suicidal intent. Repentance quickly followed, and a large drink of whiskey was taken. The stomach pump was applied within fifteen minutes. Patient was unconscious half an hour, but recovered. Death is due, in Burke's opinion, to cardiac paralysis. Several times he was able to get a response from the breathing apparatus by rhythmic lingual traction long after the heart had stopped. He never saw vomiting except in hysterical patients. The acid is quickly fatal, and he believes it to be painless, except so far as throat and lip burns are concerned. He puts no confidence in sulphates as antidotes, but believes alcohol to be of great value. The tube should be used when any appreciable amount of acid has been taken, and should be a fairly stiff one. If alcohol (whiskey) cannot be given by the mouth, it must be given generously by needle and by rectum.

Respiratory Education in the Treatment of Heart and Lung Disorders.—J. Madison Taylor criticises the usual remissness of physicians to give definite instructions along the line suggested by the title of his paper. Respiratory education is better than drugs in many clinical conditions. His observations have been based mainly on young neurasthenic patients with respiratory and circulatory troubles. Such patients should be taught to expand their lungs fully. The rate of breathing should be five seconds in inspiration and seven for expiration, and these figures gradually increased to twenty and twenty-five, respectively. These movements are also useful in abnormal conditions of the abdomen, due to deficient circulation and aeration. The patient may lie, sit or stand, and the physician should explain that the thorax should be held so that the ribs are as nearly at a right angle to the vertebral column as feasible, and that the act of breathing shall be performed chiefly by the expansion and contraction of the lower ribs, which should acquire an increasing mobility and range. After the chest has been filled and held at the highest point of tension for a few seconds, expiration should begin by the indrawing of the umbilicus, and the force shared in by all the abdominal muscles which can be elicited in the act, the chest still held high, and a steady compression exerted upon the diaphragm chiefly. When the abdominal muscles have contracted to their full capacity the lower ribs follow, and finally all the air which can be expelled is extruded. At the end of expiration a slight cough may be encouraged, which seems to finish the act.

Dupuytren's Finger-Contraction.—C. A. McWilliams gives a general review of the prevailing ideas on this disease, and relates one personal case occurring in a man of fifty-three years. Operation was performed, all constructing and restraining bands between the tendons being removed, and a perfect result ensued, the patient being able to use his hand as freely as ever. The author describes the various surgical procedures in common use. In all cases careful post-operative treatment is necessary. After two weeks of splinting, massage and passive motion should be begun. At the beginning of the disease, much may be done to check its progress by systematic massage, active and passive motions, hot air baths, hot water baths, with the application of extension apparatus at night. Any constitutional diathesis should be treated. In case the disease advances, or in somewhat more developed cases, multiple subcutaneous incisions may be made, followed by the palliative treatment just outlined. In working persons, who can scarcely find the necessary time and means properly to carry on the palliative treatment, radical operation is to be advised as the quickest and surest means of effecting a cure. It should be advised at once also in advanced cases.

Medical News, October 8, 1904.

Internal Antisepsis.—J. N. Hall declares that although surgical measures, whenever possible, should be taken for the prevention of sepsis, still there are cases which are seen too late for this or in which prevention, as far as we know, is out of question. A case in point is typhoid fever, or sepsis of so-called cryptogenetic origin. In this affection treatment through the blood stream seems at present the only resource. The ability of septic organisms to do harm lies not so much in the few that are introduced into the blood stream, as in the capacity of these few to multiply indefinitely. An antiseptic powerful enough to prevent reproduction is not nearly so strong as one capable of destroying the parent organism. It is the young plasmodia of malarial fever which are killed by quinine rather than their progenitors. If we could take the next step their propagation could prevented. The digestive tract offers a most interesting field for this work. The antiseptic effect of the hydrochloric acid in the gastric juice probably prevents many infections. Comda bacilli in any reasonable numbers cannot survive the acidulated bath into which they are plunged when they enter into the normal stomach. It is interesting just here to note the reported hyperacidity of the digestive fluids of carrion-eating birds. The millions of virulent organisms which these birds swallow become harmless. It is stated by an authority that putrefaction does not occur in the small intestine as long as the contents are strongly acid. The use of antiseptics must not be too strenuous. Acute nephritis has developed after the too free use of salol in typhoid fever. Bacteria do not seem essential to digestion, and so there need be no special fear that digestion will be seriously interfered with by destroying intestinal bacteria. Although much may be accomplished by the use of various bismuth compounds, naphthalin, salicylic acid, and other remedies, as yet no generally accepted intestinal antiseptic has been produced. In the urinary tract the use of antiseptics has met with more success. Investigators have demonstrated the entire disappearance of the typhoid bacilli from the urine under the administration of hexamethylenetetramin. Such treatment is imperative, and the results are most gratifying, in almost all cases in which there is reason to fear a destructive process in the kidneys or an ascending infection. The writer has been most impressed by the cases in which there exist certain infections caused by the colon bacillus. Some of these cases which ended fatally, showed abscess formation in the most various localities, at post-mortem. In some cases in which urinary antiseptics were given intelligently the urine cleared and recovery took place. The writer believes that these are the most brilliant examples of the influence of internal antiseptics which he has seen. In cases which might be termed "streptococcic consumption" the injection of antistreptococcic serum has been followed by most gratifying results. The writer thinks that there are good chances that there will be discovered some internal antiseptic comparable in its effects with those of the silver salts in gonorrhœal ophthalmia. He believes that, judging from the advances in the past decade in internal antisepsis, we can hope for greater discoveries in the near future.

American Medicine, Oct. 8, 1904.

Gastroptosis, with Special Reference to the Surgical Treatment; The Operation of Gastropexy.—Henry D. Beyea, after carefully studying on the cadaver the anatomic relations and the ligamentary supports of the stomach and considering the importance of the preservation of the physiological mobility of a hollow viscus, especially the stomach, devised an operation which he briefly describes as follows: The principle of this operation is that, by placing three rows of interrupted silk sutures from above downward, and from right to left through the gastrohepatic and

gastrophrenic ligaments, a single broad transverse fold or plication is formed in the ligaments, shortening these ligamentary supports and elevating the stomach to normal position. The normal ligaments are shortened and the stomach elevated to position without in the least disturbing the physiological mobility of the organ. The results of this operation have been most successful. Eleven patients who have been reported have undergone this operation. They have now been observed for periods varying from eight months to six years after operation. The convalescence after operation was in each case normal and easy. In no instance has the stomach changed in position. Among these cases, it must be said, there was no relaxation of the abdominal walls or diastasis of the recti muscles. Further work will be necessary to prove what effect this operation will have in such cases. The writer believes that the surgical treatment of gastroptosis is the only logical one.

The Mild and Abortive Forms of Typhoid Fever.—John Bradford Briggs thinks that the simplest plan of classification is to consider all cases with a maximum duration of 18 days or less as "mild typhoid," and under this head to distinguish the mildest cases; "typhus levissimus," characterized both by brevity of course and mildness of symptoms, from the cases of true "abortive typhoid," in which the general symptoms may at any time be severe, but in which the defervescence is rapid, being complete by the middle of the third week. In a majority of the cases the onset is sudden. The rise in temperature is usually rapid, and the patient with abortive typhoid is apt to be incapacitated at a period when those with typical infections are still up and about. The symptoms are not severe, although some cases with evidences of marked toxæmia become afrebile by the twelfth day. The headache, the lassitude and the other classical symptoms of the typical attack, occur in the mildest form. Roseola is present as often as in the typical forms. In many cases, however, they have to be carefully looked for. Enlargement of the spleen is as common in the mildest as in the most severe forms of the disease. The bowels are generally constipated. The catarrhal condition of the bowel wall seems to be either absent or of very low grade in the milder infections. Abdominal pain is rare. There are no special systematic studies of the blood in these cases recorded in the literature. Agglutinating substances are sometimes present in the blood at an early date. Complications and sequelæ are rare. It is not certain whether there is a tendency to relapse in patients who have had the mildest form of typhoid. The essential part of the treatment is preventive. The patient should accept the usual typhoid regimen. The writer believes in the administration of castor oil. The nourishment should be in liquid form, and isolation should be practised. In the few post-mortem examinations that have been recorded, the characteristic intestinal lesions were found. It is known that active typhoid bacilli may be carried about in the intestine of perfectly healthy people, and that they may multiply and be distributed for some length of time, and all without producing any symptoms on the part of their host. The writer concludes his paper by emphasizing the importance of the recognition and proper treatment of these mildest cases of typhoid.

Dilatation of the Stomach, with Special Reference to Forty-Eight Cases.—John J. Gilbride has found among 637 stomach cases 48 cases of dilatation. Of these, 25 were women and 23 were men. Of the women, 23 were married, but only 11 of these had been pregnant. The disease is most common between the ages of 20 and 50. The youngest of these patients was 18, the oldest 70 years old. It is necessary that the cause of the trouble be ascertained in order that the proper treatment may be instituted. Many predisposing factors have been suggested, such as overeating, irrational clothing and sedentary habits It is probable that the method of feeding is responsible for the condition of "weak stomach" found in certain families. In one class of cases atony is present; in another there is no real loss of tone of the muscle, but an increase, and to this class belong the cases of stenosis at or near the pylorus. Gastroptosis and enteroptosis are not uncommon in dilatation of the stomach. It is important in these cases not only to determine the motor power of the stomach, but also to make a direct examination of that function. For this purpose the time of digestion should be tested according to the suggestion of Leube. A test meal of soup, beefsteak and a roll are given. If the stomach is empty after seven hours, it may be assumed that the time of digestion is normal. Artificial inflation of the stomach with air or carbon dioxide is essential in making a diagnosis of dilatation. An analysis of the gastric juice gives valuable information. Blood changes depend upon the cause of the disease. The bowels are often constipated. But whatever the symptoms may be, they will depend upon the original cause of the condition. The most important symptoms are those caused by motor insufficiency, and these must be distinguished from those caused by the primary disease.

Journal of the American Medical Association, Oct. 8, 1904.

Osmic Acid Injections for the Relief of Trifacial Neuralgia.—J. B. Murphy concludes a long article on this subject as follows: Trifacial neuralgia, tic douloureux, is not the result of a pathologic entity which has so far been definitely determined. The tendency after all types of operation, with the possible exception of removal of the sensory root behind the ganglion, is to recurrence of the disease. This is probably due to the regeneration of certain nerve elements following the deep operation, and anastomosis and retention following the superficial. Sudden shocks and irritation to the terminal filaments of the trifacial not infrequently cause an immediate and occasionally a permanent cessation of the neuralgic pain. The mortality from the superficial exsections is practically *nil;* the mortality from the intracranial operations is great. The hazard is greater than should be taken in a disease which does not in itself jeopardize life. Injections of osmic acid in 1 to 2 per cent. solution into the nerve trunks relieve the pain immediately, and in a large percentage of cases for a long period of time. The injections into the superficial tissue for peripheral neuralgia should be abandoned, as the nerve trunks are easily located, and there is no danger of superficial necrosis following such operation. It should never be injected into a motor nerve or a motor nerve area, and, therefore, never into the spinal nerves, except in amputation stumps. It produces a local necrosis of the tissue into which it is injected, and even of the wall of the foramen. This necrosis does not suppurate unless the area is exposed to mouth infection. In that case the suppuration often continues for weeks, draining into the mouth, giving no special inconvenience, and in no way interfering with the final result. The best results are obtained with a 1½ to 2 per cent. solution; this should be injected in many places into the nerve trunk, and also into the foramen. All of the nerve branches should be injected —the palatine, lingual, mandibular, superior maxillary (infraorbital) and supraorbital. They can all be exposed through mouth incisions, except the supraorbital. Many times there are three or four divisions of the supraorbital and they should be searched for carefully and each injected. Occasionally it is necessary to inject the auricular branch. The posterior palatine is not so difficult to inject as one would at first imagine. The foramina can and may be injected without anæsthesia or incision. The procedure is quite painful, however, and is not certain in its results. The injections can be made with local or general anæsthesia (general preferred by the author) and are free from danger. Judging theoretically from the experience with incisions, resections, and ganglion operations, the relief should not be permanent after the injection of the osmic acid. From clinical experience up to date, however, the fact is that many cases are permanently cured. Time alone must determine the final result of this treatment.

The Lancet, Oct. 1, 1904.

A Case of Banti's Disease.—The case is reported of Drs. J. F. Strickland, J. F. Hodgson, and W. B. Anderton, their patient being a woman aged forty-six, who presented herself suffering from epistaxis due to a fall. The bleeding was stopped with difficulty. She was extremely anæmic and had an enlarged spleen. The latter was first noted a fortnight after her last confinement, five years before. The liver was slightly enlarged and tender, but no ascites or dyspnœa were present. Blood examination showed less than half the normal cell contents and only one-third the normal hæmoglobin. Dyspnœa occurred at times and the heart action was weak. The general features of the case as it progressed were those of a slowly advancing anæmia, manifestly of a pernicious type, with the continued enlargement of spleen and liver. Death finally came from exhaustion, she having had periods of restlessness, and on one occasion attempting suicide. Autopsy revealed a paleness of all the tissues and serious condition of the blood. The spleen weighed nine pounds and was permeated with fibrous bands. Lymphoid cells were fewer than usual, and few red cells were seen. Numerous granules of black pigment were present, but there was no iron reaction. The liver showed similar changes. In this organ the iron reaction was present, but slight in degree.

Medical Treatment of Deep-Seated Hemorrhage.—The paper of F. Hare is a plea for the use of amyl nitrite in hæmoptysis. The remedy is given by inhalation. Sometimes the looked-for result followed the inhalating immediately; sometimes not for ten minutes; but in thirteen attacks, twelve tuberculous and one cardiac, the bleeding ceased in all but one in three minutes. One capsule is generally sufficient, and in following attacks nitroglycerin may be given. As a rule, bleeding does not recur when once checked by the inhalation. The author thinks that the sudden heavy fall of blood pressure permits some coagulation and plugging of the leak, and that this is usually adequate to resist successfully the subsequent rise, which, likely enough, fails in consequence of the previous hemor-

rhage to attain quite its former height. If the amyl is unavailable, the author suggests a hot immersion bath. The large vasodilatation of the skin area would lead to a lessened intra-aortic resistance, a fall of blood pressure in the left auricle, and eventually in the pulmonary area. At the same time the mouth and nose should be protected from inhaling hot air; in fact, cold air inhalations may themselves check the bleeding.

Medical Treatment of Constipation by the Injection of Olive Oil.—G. Herschell believes that in suitable cases and a proper technique for the injections, that olive oil is a most useful remedy in constipation. Results of a gratifying nature follow in chronic colitis, constipation associated with spasm of the bowel, as in neurasthenia and in atony of the intestine, here combined with the use of electricity. From three to ten ounces of oil should be injected at bed time and retained overnight. It should be slowly introduced by the force of gravity. He prefers a glass funnel hung in a metal frame and connected by a rubber tube with a nozzle of large bore and well-rounded tip. A spring clip regulates the flow. The amount at first should be restricted to five or six ounces, but this can gradually be doubled. After a while the injections can be given on alternate nights only.

A Retropharyngeal Blood Cyst in a Case of Pupura Hæmorrhagia.—The patient of P. S. Blaker was a girl of eight months. A diagnosis of retropharyngeal abscess was made, incision of the swelling evacuating not pus, but blood. The hemorrhage continued, however, from the area until the patient died, all efforts at hæmostasis proving fruitless. In view of the symptoms presented by the child previous to the pharyngeal swelling, a diagnosis was made of purpure hæmorrhagia. Nevertheless, the obstruction to breathing was so great that operation was imperative. The author is inclined to believe that intubation ought to have been tried, though it would have proven very difficult, or a preliminary tracheotomy might have been done and the swelling incised, this followed by the plugging of the cyst cavity.

A Case of Anilin Poisoning.—P. G. Harvey reports the case of a woman of twenty-seven years suffering for two months from painful swelling of the lips and gums, dyspnœa, and faintness. Later the buccal mucosa became discolored, and vomiting came on immediately after eating. A diagnosis of ptomain poisoning or local infection from unknown causes in the mouth was made, and on investigation it was found she was in the habit of using an anilin pencil, which from time to time she moistened in her mouth. Discontinuance of the pencil-sucking habit led to a speedy cure.

Some Observations Pointing to an Intra-Corpuscular Stage of Development in the Trypanosome.—E. J. Moore has noted the life history of the trypanosome in cattle, and has found that the parasites were very often found in pairs, and observed them travelling across the slide towards one another; the parasites also exhibited motions of a very peculiar nature, the body substance becoming repeatedly retracted to either extremity, and sometimes at the same time to both extremities, forming one or two spheres, with a bright spot in the center. These movements were sometimes followed by the death of the parasite, and it is a matter of interest that in dying the animal invariably assumed a globular shape; this probably accounts for the difficulty in finding trypanosomes post-mortem, even when they have caused the death of an animal. In the cases of parasites which survived longer, there was often a definite series of movements of the posterior portions of the body substance to the extremity of the tail, the tail-spot being jerked along with the protoplasm, which then gradually returned to its original position, the tail-spot remaining stationary against the side of the sheath, while the protoplasm rippled forward past it; the result of the movements was that the tail-spot became slowly pushed towards the hinder extremity. All the movements of the parasite seemed to be purposive and directed towards getting rid of the tail-spot, which seemed to constitute a source of irritation.

Berliner klinische Wochenschrift, Sept. 12, 1904.

"Some of My Opinions."—Jonathan Hutchinson believes that the most convenient method of administering mercury in syphilis is in the form of pill, in small doses frequently repeated (hydrangyrum cum creta, one to two grains for a dose). The course of treatment should be a long one, extending without interruption for from one to two years. In order to prevent diarrhœa, one to two grains of Pulv. Ipecac Comp. should be combined with each dose of mercury. This treatment should be begun as soon as the diagnosis of chancre becomes reasonably certain, and, once begun, should be resolutely persevered in. He allows marriage after the expiration of two years from the date of chancre and never earlier. The syphilitic virus probably persists in the ovaries longer than in the testes, and it is doubtful whether women who have suffered from syphilis can ever be guaranteed as regards uncontaminated offspring. A great many instances of second attacks of syphilis have come under the author's notice, several within very short periods, that is, within one or two years. Other opinions of the author are: That the eating of badly cured fish is the one sole cause of the origin of leprosy, and that it is not "contagious" either by touch, breath or insect bites. That leprosy may be communicated from one individual to another (1) by an infant taking milk from a leprous mother's breast, or (2) by a person eating food which has been contaminated by a leper's hands. That gonorrhœa in all stages is best treated by parasiticide injections. The more acute the symptoms, the more necessary is the chloride of zinc injection. That gonorrhœal rheumatism occurs almost solely in those who inherit gout, and that it is common in different communities in ratio with the prevalence of gout. That rheumatoid arthritis, or "rheumatic gout," occurs chiefly in the descendants of the gouty. That alopecia areata (tinea decalvans) is usually a sequel of ringworm (tinea tonsurans), and is common in ratio with the prevalence of the latter. That the fungus in the different forms of tinea is probably the same, and however great may be the apparent differences, they are not specific. That when tertiary syphilis stimulates lupus it is because the patient is tuberculous as well as syphilitic. That the various forms of malignant disease (cancer, sarcoma, etc.) depend not upon parasitic infection, but upon heritable proclivities of tissue which are essentially the same for all, and that the different forms are transmutable in inheritance. That the long continued use of arsenic, whether externally or internally, increases the tissue proclivity to all forms of malignant growth. That chimney sweeps' cancer is the consequence of the application of soot containing arsenic. That certain other mineral drugs may share with arsenic as tending to increase the proclivity to cancer.

Eosin Phototherapy.—Pick and Asahi report on a series of twenty-two cancers treated by a combination of eosin application and sunlight. The lesion in question comprised lupus, tuberculosis, cutis verrucosa, tricophytosis, scrophuloderma and rodent ulcer. The affected areas were daily painted with 1 per cent. eosin solution and exposed to the sunlight. In all of these cases the results were very encouraging, and caused gratifying improvement, although in its present form the procedure cannot yet be called curative.

Berliner klinische Wochenschrift, Sept. 19, 1904.

True Rabies or a Modified Inoculation Form?—Heydenreich describes the case of a kitchen-maid who was slightly bitten by a young dog and was immediately subjected to the Pasteur treatment. Twenty-four injections were given in twelve days; from the sixth day she began to suffer from malaise, nausea, slight cerebral disturbance and stupor. These symptoms increased in severity, and obstinate constipation, paralysis of the detrusor vesicæ, dyspnœa, great mental depression, with paresis of the face, tongue and pharynx developed. After a month of these symptoms the physical condition began to improve gradually, but the patient became profoundly melancholic, the intellect was clouded, and ten months after the injury was received she died a total idiot. The author believes that in this case the symptoms were due to the inoculations, for the disease began to show itself on the thirteenth day after the bite, an unprecedentedly early date for rabies to develop, especially as the bite was hardly a scratch and was on the hand. What is still more important, another servant in the same household was bitten by the dog at the same time, receiving much more severe injuries, but as she greatly dreaded the Pasteur treatment, she concealed the facts until later. This woman developed no symptoms whatever. It could not be determined whether the dog were really mad or not, as it had been promptly killed and no autopsy made.

Epithelioma and Lupus in a Diabetic Patient, Treated with the X-Rays.—Levy Dorn reports a case in which a lupus of the buttock of twenty years' standing underwent malignant degeneration and progressed as an epithelioma. For six years the patient had well marked diabetes, as much as seven per cent. of sugar being present before dietetic treatment was begun. Treatment of the local lesion by the usual means was ineffectual, and the ulcer measured more than two inches each way. Great improvement attended the first application of the *x*-rays, followed by a stationary period, and then complete healing of the ulcer, after the treatment had been pushed with sufficient energy to produce a moderate reaction. The case is interesting in showing that the *x*-ray is as effective in combatting combinations of lupus and carcinoma as it is for these conditions separately, and that even marked diabetes is no contraindication for its employment.

Münchener medizinische Wochenschrift, Sept 13, 1904.

Investigations on the Gastric Juice.—Bickel describes observations on the composition of the gastric juice made by the aid of the ultra-microscope. The secretion was obtained from dogs having a gastric fistula according to Pawlow, and was filtered until perfectly clear. The highest powers of the ordinary system show practically nothing in a drop of this fluid, but under the ultra-microscope myriads of faintly luminous granules are seen on a dark background. Boiling the juice and filtering off the resulting precipitate somewhat diminishes the number of the granules, as does also the interpolation of a Nicol's prism. Pure water, salt solution and dilute hydrochloric acid do not show such granules, and the author takes the view that they are connected with the ferments of the juice. The gastric juice is therefore not to be considered as a simple solution, but as an emulsion. On determining the freezing point and electrical conductivity of portions of gastric juice obtained at intervals during the process of digestion, it was found that the results were inconstant, and the author concludes that the juice differs in its chemico-physical properties at different stages of digestion, and that it is often more concentrated than the blood itself.

Inoculation Tuberculosis Accompanying the Morphine Habit.—Bruns has found four cases of cutaneous tuberculosis in the literature, which were due to inoculation by means of the hypodermic needle. His own case was that of a patient with an advanced pulmonary lesion, who had become a morphine habitué. He was accustomed to moisten the site of the proposed injection with saliva, and to blow through the needle each time before use. For several years this method had no disagreeable results, but finally nodules began to develop in the regions where the punctures were made, and these then broke down and became shallow, discharging ulcers. Cold abscesses also formed in the skin, and the pus injected into guinea pigs gave rise to typical tubercular lesions. In order to determine whether the infection had actually been from without, or whether the needle punctures had merely formed spots of least resistance which had succumbed to hematogenous infection, injections were made under aseptic precautions on one side of the patient's chest, and on the other following his own older technique. In this situation lesions similar to those already observed soon appeared, while on the other side no reaction was produced.

Radiotherapy for Uterine Tumors.—Deutsch has treated four cases of advanced myoma uteri with marked success by means of the *x*-ray. The tumors decreased in size and the patients were freed from symptoms. In particular, the increased frequency of micturition subsided after only a few treatments. A case of inoperable carcinoma of the uterus was much benefited, but in another instance in which an ovarian tumor was associated with a fibroid, the latter alone was appreciably affected by the treatment. The method seems very promising in cases unsuited to operation, its only drawback being the patience it requires on the part of the physician and patient.

Münchener medizinische Wochenschrift, Sept. 20, 1904.

The Bacteriology of Acne Vulgaris.—Söllner and Kreibichs have studied the bacteriological flora of acne and comedo in an attempt to reconcile the conflicting statements of various authors in regard to organisms that have been described as the causative agents of these lesions. Twenty different cases of comedo and acne-cocci were studied culturally and in regard to their hemolytic and agglutinating properties, with the result that it seems clear that the pus formation accompanying acne cannot be due to either the staphylococcus pyogenes aureus or albus. The part played in producing the acne lesion by the various white cocci observed is still undetermined. Attempts to identify the acne bacillus described by Unna were also unsatisfactory, and the authors conclude that many varieties of microorganisms occur in acne, but that it is impossible to determine their etiological relationship to the disease.

The Danger to the Cæcum Attending Obstruction of the Colon.—Kreuter calls attention to the fact that in cases of extreme dilation of the colon due to volvulus, stenosis, tumors, etc., the cæcum is almost always the seat of the greatest distention. This extreme dilation may lead to the greatest interferences with the nutrition of the part, to ulceration and even perforation. Four factors contribute to the production of this feature—the fact that the ileocæcal valve is competent, that the wall of the cæcum is the thinnest and least resistant part of the large intestine, that the continuity of the latter is interrupted through the occurrence of kinks at the colic flexures, and that the cæcum normally contains the greatest amount of gas and fecal material in the intestine. The danger of this complication should always be kept in mind, and the author's point is illustrated by a case in which fatal peritonitis followed perforation of the cæcum in a patient suffering from a stenosis situated at the splenic flexure.

Deutsche medizinische Wochenschrift, Sept. 15, 1904.

The Effect of Photodynamic Substances on the Action of the Röntgen Rays.—Kothe was led to experiment with various coloring matters in relation to their effect on the *x*-ray. It was found that photographic negatives made with plates that had been half immersed in blue-green, green or violet dyes gave very faint and blurred images on the side of the plate so treated, whereas the similar use of orange or red solutions was without effect. The injection of weak eosin solutions (1-100 to 1-1,000) under the skin before exposure to the *x*-rays greatly increased the reaction, and warts subjected to this preliminary treatment decreased in size more rapidly than others not so prepared. Experiments with rabbits gave similarly positive results, parts of the body previously injected with eosin soon showing a reaction, going on to ulceration and sloughing, while the uninjected control regions were unaffected. The author considers that practical use may be made of this property in cases in which it is desired to bring about a strong reaction quickly, and that it will prove especially applicable in the treatment of malignant growths.

The Treatment of Syphilis.—Rosenthal says that syphilis is a disease which can be cured with absolute certainty, and that uncured cases are evidence of insufficient treatment. Mercury is the only drug to be regarded as a specific, and in spite of the older views to the contrary, iodine must fall back into a merely secondary place and cannot be regarded as a substitute for mercury. The abortive treatment has little to commend it and is open to many objections; but while in most instances security of diagnosis is essential to proper treatment, under some conditions it is permissible to begin constitutional treatment early. Such are extragenital chancres situated on the lip, nose or eye, for example, where pain or the subsequent danger of deformity must be combatted, women infected during pregnancy, etc. Of the two plans of treatment in vogue, the symptomatic and the chronic-intermittent of Fournier, the latter is by far to be preferred. It must always be remembered, however, that it is the patient and not the disease that is being treated, and individualization is essential. The danger of over-mercurialization is slighter than is supposed, and energetic treatment is always required. Inunctions are unscientific because of their inexactness and have many disadvantages, whereas hypodermatic injections are superior to them, both theoretically and practically.

A Clinical Report on Phototherapy After Sensibilitization.—Forchhammer gives the results of an extensive series of observations made at the Finsen Institute, following a new plan. As is well known, the rays at the violet end of the spectrum possess greater bactericidal power than the green, yellow and red rays, but are inferior to these in penetrating power. Dreyer has found that by the use of certain fluorescent substances, such as erythrosin, which are called sensibilitizers, it is possible to make the yellow and green rays actively bactericidal without sacrificing their penetrating power. In order to test the practical utility of this method, twenty-three lupus patients were treated by the author in three hundred and fifty sessions. A sterile one to one thousand solution of erythrosin in physiological salt solution was injected cutaneously or subcutaneously, according to the seat of the lesion, and four to eight hours later the exposure to the light was made. The injection was not accompanied or followed by any reaction, but the light treatment caused intense pain and a severe local reaction, which was slow to subside, and in some cases went on to necrosis. The therapeutic results, on the other hand, were less satisfactory than with the old method, even in the case of deep-seated lesions. Attempts to diminish the reaction by reducing the amount of erythrosin, or by lessening the intensity of the light rays were unsuccessful, and the author reports the results as a warning to others whom the plausibility of the theoretical considerations involved might tempt to try similar experiments.

Deutsche medizinische Wochenschrift, Sept. 22, 1904.

The Teeth as Portals of Entry for Tuberculosis.—Partsch states that it is singular, considering the frequency with which tubercle bacilli are present in the mouth, that infection by way of carious teeth does not oftener occur. He describes the case of a girl of fourteen, who suffered for some time from a painful swelling of the jaw, accompanied by enlargement of the submaxillary glands. It was only after protracted treatment that it was recognized that the condition was a tuberculous periodontitis, which had its origin in the root of a decayed tooth, spread like an ordinary inflammation through the jaw, and caused swelling of the neighboring glands, later spreading to the cervical nodes also.

What Should the Treatment of Complete Rupture of the Uterus Accomplish?—Küstner says that the question of the proper treatment of this injury is still open to dis-

cussion. A few years ago the general opinion was in favor of laparotomy, or vaginal extirpation of the uterus, but at present the conservative treatment is again gaining ground. In considering the statistics caution is necessary in drawing conclusions, for this accident more than almost any other requires to be judged on the merits of each particular case. As the result of seven cases which the author treated by laparotomy, he expresses himself as in favor of this plan, even though but two of his patients recovered. He believes in free incision in all cases, whether the laparotomy is demanded for the purpose of checking hemorrhage or not, a careful search for all pools of blood, meconium and liquor ammnii in the peritoneal cavity, especially in the easily overlooked recesses in its upper part, and careful removal of these foreign fluids by sponging. The abdominal cavity is not to be flushed with salt or any other solution. Hemmorrhage is carefully controlled by ligature, and the rent in the uterine well sutured. If the bladder is torn, this should be sutured also. Hysterectomy is to be done only in exceptional cases, as the patients are usually not in condition to stand it. In some posterior ruptures it may be better to drain vaginally instead of suturing the uterus. A large Mikulicz tampon should in all cases lead from the uterine tear out through the abdominal incision.

French and Italian Journals.

Researches in Relation to the Agglutination of the Streptococcus in Scarlatina.—Georges Bourcart concludes from his studies that the agglutination of the streptococcus of scarlatina, by scarlatinal serum, may be brought about; that it may even be clearly positive; but that also, under the same conditions, the results are sometimes doubtful, and may be negative, even with the serum of the same patient. It is difficult to prove this agglutinative power by reason of the non-motility of the streptococcus, and the writer thinks that the determination of this phenomenon, simple though it is, when the bacillus is very motile like the bacillus of Eberth, becomes extremely uncertain when the micro-organism in question is non-motile. This reaction, after the employment of diverse methods, remains variable and inconstant. Any serum, normal serum as well as the serum of patients suffering from other infections than scarlatina may have anagg lutinative action on a streptococcus of scarlatina. This agglutinative power, inconstant and variable, may be in the comparative researches, weaker than that of the scarlatinal serum, but it may perchance also be equal to it. The author declares that these results do not authorize us to attribute any value to sero-diagnosis in scarlatina, and cannot lead to conclusions on the subject of the specificity of the streptococcus in scarlatina.—*Revue Française de Médecine et de Chirurgie,* September 5, 1904.

Concerning the Influence of the State of Health on the Freezing Point of Milk.—Bouchard presents the conclusions which Guiraud and Lasserre have drawn from their recent experiments with milk. They have found the freezing point of pure milk, taken from well animals, constant, between —0.55 and —0.56. This agrees with the work of Parmentier. The artificial addition of water could always be detected. But the special point of interest in this work is that of the influence of the state of health of the animal giving the milk, on the freezing point of the milk. The milk from both women and cows has been tested with the following results: Milk from a woman suffering with jaundice, on the first trial, —0.58; on the second trial it was the same. Milk from an albuminuric woman on the first trial froze at —0.59; on the second, at —0.58. The freezing point of milk from a syphilitic woman showed the freezing point —0.61 at two trials. Milk taken from a tuberculous woman froze at one time at —0.60, and a second time at —0.61. Milk from a cow, which had reacted to tuberculin, showed a freezing point of —0.60; that from a cow with tuberculous mammitis, —0.59. All of the milk with a pathological origin which these experimenters have been able to analyze have shown a freezing point sensibly lower than that of normal milk. All of these experiments, the investigators state, have been made with a freezing mixture of constant composition (one part of sea salt to four parts of cracked ice).—*Le Bulletin Médical,* September 3, 1904.

Cold Abscess of the Tongue.—Salva Mercadé states that cold abscess is among the rarer forms of tuberculosis of the buccopharyngeal cavity. The writer reports a case of this nature that came under his care. The patient was a small girl of 8 years, who came into Lannelongue's clinic. On the left side of the tongue there was seen a small whitish tumor, which at first sight resembled simply a purulent bulla. The tumor was about midway between the tip and the root of the tongue, and 1 or 2 millimeters from the median line which appeared to be curved to the right with the concavity toward the tumor. The growth was about the size of a large pea. It was covered with thin mucosa, and was clearly fluctuating. The evolution of the abscess was like that of a cold abscess, without pain, without fever, and without showing any special symptom. The mother had noticed it only 4 or 5 days before. Since that time the abscess had not changed. The child ate as usual and suffered no discomfort. No enlarged glands could be found. There was no cough, nor did auscultation reveal any abnormal sign. The lesion was incised and scraped as would be done in the case of a cutaneous gumma. It was very superficial. The pus from it was thick, greenish white in color, and give the macroscopic apeparance of tuberculous pus. The microscope revealed no sign of any pathogenic organism.—*Gazette des Hôpitaux Civils et Militaires,* September 8, 1904.

Pneumonie Phlebitis.—René Gaultier and Maurice Pierre declare that phlebitis occurs frequently enough in the course of pneumonia to be considered one of the possible complications of this disease. The writers believe that it should be classified as a form of infectious phlebitis due to the pneumococcus. It has been noted most often in moderately severe cases. It develops especially at the beginning of the period of convalescence. Patients frequently recover from this complication, although, on the other hand, the vein is often blocked by a clot which forms rapidly and consequently is only slightly adherent. Death by embolism is quite possible under such circumstances. The prognosis, therefore, is grave. This complication ought to be considered at a period of the disease, when it would appear that the patient is already beyond the danger line.—*Gazette des Hôpitaux Civils et Militaires,* September 3, 1904.

The Value of the Leucocyte Formula in the Liquid of Blisters.—Constatino Tommasini has taken up the method proposed by Roger for obtaining the leucocyte formula in various diseases by examining the liquid obtained by producing a blister with cantharides, and has made experiments in 63 cases of normal and diseased subjects. He finds that the blister is not formed in all cases in the same manner, and in 10 per cent. of the cases vesication was not successful. The fact that the cantharides produces an active inflammation of the skin causes the polynucleated neutrophiles to be most frequent in the liquid, and the mononucleated and lymphocytes to be few in number. He concludes that (1) the method of Roger is not reliable. (2) Although it shows a deficiency of eosinophiles in fever and grave general conditions, this gives no indication that the case itself does not give; and in other diseases there is no characteristic cytological formula to aid in diagnosis. (3) The cytological formula has no real dependence on the stimulation of the hæmatopoietic organs, and their capacity to react, but simply on the chemiotactic action of the local blister.—*Rivista Critica di Clinica Medica,* August 20 and 27, 1904.

Influence of the Lymphatic Glands on Immunity and Serum Therapy.—Guiseppe Evoli has studied experimentally the effect of the lymphatic glands on the passage of germs from one part of the body to another. He goes over the theories of the production of immunity and the different influences that oppose themselves to the action of bacteria. He divides these as follows: (1) Organs that oppose the penetration of the bacteria: skin, mucous membranes, etc. (2) Organs which oppose the multiplication of microbes and their deleterious action: spleen, liver, etc. (3) Organs which aid the elimination of the microbes and their toxic products: kidneys, lungs, sweat glands, etc. The lymphatic glands he classes among the organs that protect the organism by arresting the passage and retarding the spread of microbes, while allowing them for some time to retain their virulence. The microbes remain in the lacunæ of the reticulum of the glands. The author concludes from his experiments that the lymphatic system, by the richness of its distribution, is one of the most important means of defense against microbes. It retards their passage for a time, during which the organism does not feel their effect. This is due to the anatomical structure of the lymph glands. There is an antimicrobic influence in the lymph which attenuates the virulence. These facts are confirmed by serum therapy. —*Giornale Internazionale delle Scienze Mediche,* August 31, 1904.

A Case of Heroin Addiction.—Teofilo Montagnini reports a case of heroin habit, which he considers of especial interest, because heroin has been recommended to us as a drug that has not the danger of producing a habit, and that can be successfully used to assist the patient in breaking off the morphine habit. The patient, forty-seven years of age and in easy circumstances, began the use of morphine for severe uterine colic, and soon became a slave of the drug. Heroin was used as a substitute, in order to control the painful symptoms while giving up the morphine. The heroin had to be increased rapidly in amount, until after one year she was taking 60 centigrammes per day. The patient would even stop in the public street to take an injection of heroin; from being well-mannered and neat in her dress she became careless, slovenly, and vulgar. She lost all capacity for work or exertion of any kind, and became melancholy. There were grave disorders of the nervous system, tremors,

staggering, diminished pain sensibility; cardiac disturbances, weakness and slow pulse; digestive disturbances, loss of appetite, obstinate constipation, dryness of the pharynx, colic; renal disturbances, oliguria and presence of albumin; and general denutrition. When the drug was withdrawn gradually she suffered from vomiting, loss of sleep, and violent mania. After entering a sanatorium and having a uterine polypus removed, she was finally cured permanently of the habit.—*La Riforma Medica*, August 30, 1904.

Annals of Surgery, August, 1904.

The Combined Transverse and Longitudinal Incision in Laparotomy.—Lewis A. Stimson writes of his personal experience in at least 150 cases. The line of incision is a shallow curve, concavity upward, and crosses the median line three or four centimeters above the symphysis pubis. The sides extend toward the anterior superior spines, but stop well short of them, the extent depending upon the purpose of the operation, and the amount of fat in the abdominal wall. The aponeurosis of the external oblique is divided in the line of incision, as is also the internal oblique or "sheath of the rectus." The writer generally plans not to carry the incision of the aponeurosis beyond the outer border of the rectus, and, if more room is needed, to extend it along that border upward rather than transversely. The flap is then drawn sharply upward, and the abdomen is opened in the median line in the usual manner. The operation having been completed, the wound is closed by suture of the peritoneum and of the aponeurotic layer posterior to the recti, when it can be readily identified and secured; and if the recti tend to fall apart, two or three points of suture may be placed in them. The aponeurotic flap is secured in place by chromic catgut sutures for an inch or two on each side of the median line, and the remainder by plain catgut, interrupted or continuous. Sometimes he unites the two layers separately, and sometimes includes them in the same sutures. The skin is closed as usual. The scar was inconspicuous and freely movable in all except one case. In no case was there any weakness of the abdominal wall, nor any tendency to hernial protrusion.

Peptic Ulcer of the Jejunum.—A. W. Mayo Robson says that the true cause of peptic ulcer, whether gastric, duodenal, or jejunal, is probably a mild form of sepsis leading to gastritis and excess of free HCl in the gastric juice, though traumatism has been assigned as a cause but without adequate reasons. Peptic ulcer is distinctly one of the sequelæ to be reckoned with after gastroenterostomy; curiously enough it does not occur after pyloroplasty. As regards the frequency of peptic jejunal ulcers, out of 136 posterior gastroenterostomies which he has personally performed, he has not met with one example, nor has one occurred among 100 posterior gastroenterostomies performed by a colleague. His own case occurred after an anterior gastroenterostomy, one out of thirty that he had performed. The symptoms in his case were evidently chiefly referable to a perigastritis and extensive adhesions and the intense agonizing pains at times seemed to bear no relation to food. Hemorrhage was a distinct feature, and there was a well-marked tumor at the site of perforation. Greater attention to oral asepsis and to the condition of hyperchlorhydria subsequent to operation is advisable, and in this way the very serious complication of peptic ulcer in the jejunum and relapses in gastric ulcer might be prevented. There can be no question as to the desirability, nay, as to the absolute necessity, of operation, which ought not to be delayed too long.

The Treatment of Post-operative Vomiting by Gastric Lavage.—Charles S. White states that during anæsthesia there is a condition of atony of the stomach walls, together with an exudate of chloroform or ether into the stomach, acting as an irritant, and there is formed in their presence an increased amount of toxic substances. The only method which has given uniformly good results in his hands has been lavage of the stomach immediately after the anæsthetic is stopped and before the patient leaves the table. It is essential that the patient should be well under the anæsthetic at the time the tube is inserted. There are three conditions in which this prophylactic treatment is indicated. In cases in which there has been insufficient time to prepare the patient. Such patients often have their stomachs distended with food. In cases in which the anæsthesia has lasted an hour or longer. In cases in which the patient previous to operation has suffered from attacks of nausea and vomiting, or chronic gastritis. It is contraindicated in operations upon the stomach and in very young children.

Unsuspected Lesions in Movable Kidneys Discovered During Nephropexy.—Frank E. Taylor reports five cases from which it may be assumed that a movable kidney is not uncommonly the seat of some lesion which is quite unsuspected from a clinical examination of the case. If a patient suffers from a movable kidney which gives rise to definite symptoms, there is absolutely no reason why relief should not be obtained from a well-performed nephropexy. The cases reported constitute a plea from the more frequent performance of nephropexy for movable kidney.

Transverse Ectopy of the Testis.—Albert Ashton Berg reports the following case: M. F., aged thirteen years, has had a left-sided rupture since birth, which was always reducible. Upon admission to hospital the internal organs were found to be healthy. The right side of the scrotum was poorly developed. There was a large scrotal hernia on the left side, the hernial orifice being large, and the epigastric vessels lay along its inner margin. At the bottom of the left half of the scrotum was a fair-sized testicle; its free concave border pointed downward. From its right pole a normal-sized cord passed upward to near the root of the penis, then curved sharply to the left, and was lost near the opening of the hernial ring. On slight coughing, a small mass, size of an almond, presented at the left extended ring, and it could be pulled down into the scrotum. Pressure upon it gave the testicular sensation and a cord passed from it into the hernial ring. The right external inguinal ring was very small, and no cord could be felt entering it. On violent coughing several loops of intestines prolapsed through the left inguinal canal, pushing the smaller testicle before them, but not affecting the position of the larger and stationary one. At operation for radical cure of the hernia, both cords were found to pass through the left inguinal canal. The testes were of unequal size. The smaller occupied the upper part of the sac, and its cord had a distinct mesentery; it passed up into the left inguinal canal, through the internal ring, across the space of Retzius, to the right inguinal region, whence it descended to the pelvis. The larger testicle lay in the bottom of the sac, its cord passed up into the left inguinal canal, and descended on the left side of the bladder to the pelvis. The right inguinal was found to be closed. The scrotum showed no evidence of division into two compartments. Both testes appeared normal.

Physiological Salt Solution.—Frank S. Matthews says that the use of salt solution by the hypodermic or intravenous method seems constantly widening, yet comparatively little attention is paid to the constitution of the fluid used. The fluid used should be one that will not interfere with the performance of the blood functions nor injure the body cells, and as an index of the effect on cells in general he takes the effects on red blood-cells. If the solution is too concentrated the red-cells shrink, if too dilute they first swell and later part with their hæmoglobin. The question of swelling or shrinking of the cells is determined by the osmotic effect, and not by the chemical composition of the fluid or actual weight of dissolved matter. The osmotic behavior of blood-plasma and saline solution is shown by a method based on the fact that two solutions having the same freezing point have the same osmotic pressure, irrespective of the nature of the dissolved substances. The freezing point of human blood is 56° C. In health it varies but slightly from this figure in either direction. A depression of the freezing point of .03° or .04° C. may indicate a considerable renal insufficiency. The point to be emphasized is the constancy in health of the freezing point, and consequently of osmotic pressure. Hæmatocrit determinations of the salt solution in which red cells neither swell nor shrink give .9 per cent. as the proper concentration. A .9 per cent. solution of sodium chloride is found, too, to freeze at about the same temperature as blood-plasma. Chemical analysis of the plasma, computing the sodium as a chloride gives .84 per cent. as the amount of salt in human plasma. From these determinations it is clear that the osmotic pressure of blood is equivalent to that of a sodium chloride solution of from .84 to .0 per cent. concentration. In view of these facts, it seems remarkable that the impression is so widespread that a .6 per cent. salt solution is "physiological." This solution is isotonic with frog's corpuscles, and it seems to have been assumed to be on that account innocuous to human corpuscles. It is better not to call a solution used for infusion "normal salt solution," as "normal solution" has a definite chemical significance in no way related to the solution under co-consideration. Even "physiological" solution admits of some ambiguity. For instance, such a solution for use in the conjunctival sac should have a concentration of 1.4 per cent., since that is the concentration of human tears.

Chinese Sanitation.—Arthur Stanley says that, although the Chinaman is sometimes spoken of as the most unsanitary of individuals, he would be a poor observer who would hold that Chinese sanitation is not better than that of mediæval Europe. Were China imbued with the true scientific spirit she would become perhaps a model of sanitation, because the methods of living of the people are essentially good. The prolonged national life of the Chinese and their great population is an unanswerable argument indicating sound sanitation.—*The China Medical Missionary Journal.*

Book Reviews.

Die Tuberkulose als Volkskrankheit und ihre Bekämpfung durch Verhütungsmassnahmen Ein Mahnruf an das deutsche Volk. Von Dr. Max Salomon, Sanitätkrat in Berlin. Berlin: S. Karger, 1904.

This monograph is merely a duplication of what has been written in many languages by many authors. The standpoint of the author is, however, a thoroughly scientific one, though his pages are especially designed for the laity. The advice he gives is sound and well systematized.

An Index of Symptoms as a Clew to Diagnosis. By Ralph Winnington Leftwich, M.D., Late Assistant Physician to the East London Children's Hospital, Author of "Syphonage in the Large Intestine." Third Edition. 400 pages. New York: William Wood & Company, 1904.

The third edition shows the addition of over 130 pages to its predecessor and about fifty new symptoms. The lists have been enlarged and seem practically complete, thus affording those who consult its pages an excellent guide when they are seeking all possible explanations of a given symptom. For students who are just beginning their clinical experience, the book could be of use every day; to the practitioner who is puzzled, it will refresh memories of the more uncommon diseases and afford a clue to diagnosis which otherwise might not be made. It is the pioneer work of its kind, and the author is to be congratulated on placing so much before his readers in such a small space.

International Clinics. A quarterly of Illustrated Lectures and especially prepared original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other topics of interest to students and Practitioners. By leading members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, Pa. Volume II, Fourteenth Series. Philadelphia: J. B. Lippincott Company, 1904.

This issue of the International Clinics contains amongst other valuable material, an excellent illustrated article by Dr. Ch. F. Mason on "The Spread of Diseases by Insects, with Suggestions Regarding Prophylaxis." The article is well written and shows that the writer has devoted considerable attention to the subject. The other articles are all carefully selected on subjects to interest physicians and surgeons of almost any specialty, as well as the general practitioner. They are divided under the headings of diseases of warm climates, treatment, medicine, surgery, pediatrics, and rhinology.

The Lymphatics. By G. Delamere, P. Poirier and B. Cuneo. Authorized English Translation by C. H. Leaf. Chicago: W. T. Keener & Co., 1904.

This book is a section of a French work on anatomy, edited by Poirier and Charpy. The first part, on the general anatomy of the lymphatic system, is by Delamere; the second, on the regional lymphatics, is by Poirier and Cuneo. All of these authors have achieved claim to recognition in their particular fields. The process of injection by Prussian blue, known as Gerotta's method, has been largely employed by the authors and has afforded a means of studying the lymphatics in certain parts of the body which were not well adapted for injection by mercury in the usual manner. The claim is made by the editor of the work that this is not a general review or a compilation, but is a record of opinions which are based on the result of personal researches. The work consists largely of anatomical description, but very valuable additional features are the historical notes, complete bibliographies, and notes on the technique of injection and dissection of various groups of lymphatic vessels. The book contains a fair number of original illustrations. The translation closely follows the original French. From a practical point of view, a thorough knowledge of the histology, arrangement, and distribution of the lymphatics has become very essential and the book will prove a valuable work of reference.

A Short Treatise on Anti-Typhoid Inoculation. Containing an Exposition of the Principles of the Method and a Summary of the Results Achieved by Its Application. By A. E. Wright, M.D. (Univ. of Dublin), Late Professor of Pathology, Army Medical School, Netley; Pathologist to St. Mary's Hospital, Paddington, W. Westminster: Archibald Constable & Co., Ltd.; Chicago; W. T. Keener & Co., 1904.

This treatise comprises a series of papers recently published in *The Practitioner* and now put into book form. The author gives in the first chapter the general theoretical principles in obtaining immunization, while in the second chapter he deals more particularly with immunity in typhoid fever. The second half deals with the practical technique and results of his well-known methods. He is evidently desirous of a just judgment, and has been very careful in the use of his statistical records. These records embrace over 400,000 doses of antityphoid vaccine, but still a definite conclusion is impossible, and the army authorities of Great Britain still seem at variance regarding the value of the method, knowing that those who subject themselves to protective influences are the very ones who would reduce the causes of infection to a minimum, while the ordinary soldier would drink water from which he had been specially warned. However, as a contribution, it merits the attention of all experimenters in that particular field and contains many improvements, *e.g.*, the technique for measurement of the content in protective elements of small blood samples.

Diseases of the Stomach and Their Surgical Treatment. By A. W. Mayo Robson, F.R.C.S., and B.G.A. Moynihan, M.S. Lond., F.R.C.S. Second Edition. 508 pages. New York: William Wood & Company, 1904.

The rapid advance made within the past few years in the surgical treatment of diseases of the upper abdomen has necessitated the publication of the present revised edition. The experience of the authors in over 600 operations on the stomach has permitted them to perfect the technique and to come to more definite determinations regarding the procedure to select under the differing circumstances. The authors seem to prefer the operation of gastrectomy in cancer of the stomach if the conditions permit. However, it is in non-malignant disease that the special surgical triumphs are particularly noticeable, and the markedly reduced mortality will make the internist far more willing to trust cases of hæmatemesis which resist medical treatment to the surgeon's hands, not only for the most urgent conditions but as the one means which will give a probable cure.

Although the work will be chiefly read by surgeons, it is the duty of medical practitioners to study a book of this character, for the older attitude toward operative interference must of necessity change, and the work before us will give many valuable hints regarding the diagnosis, medical treatment, and the indications of the time when medical means alone cease to be advisable—in fact, become criminal procrastination.

Food Inspection and Analysis. For the Use of Public Analysts, Health Officers, Sanitary Chemists, and Food Economists. By Albert E. Leach, S.B., Analyst of the Massachusetts State Board of Health. 787 pages and 278 illustrations. New York: John Wiley & Sons. 1904.

This is a thoroughly good book and one which will fill a previously existing want. The number of recent works on food analysis is comparatively few, and the reviewer knows of none of them which covers the subject as well as the book under consideration. Many valuable data in regard to the analysis of foods, which had previously existed only in magazines, monographs, and government bulletins, have been compiled by the author and rendered readily available in this book. For reference by public analysts and others engaged in food examination, this work will have great practical value. It is clearly and concisely written, and good judgment and discretion have been used in its compilation. The different subjects are treated comprehensively, yet without superfluity. The various methods of procedure detailed are such as have stood the test of general practice, and have the merit of simplicity and ease of execution. The author is fortunate in having avoided the temptation, in preparing a work of this sort, of including a large number of methods which possess a value largely academic and which are rarely, if ever, employed in actual laboratory practice.

A Text-Book of Diseases of Women. By Charles B. Penrose, M.D., Ph.D., Formerly Professor of Gynecology in the University of Pennsylvania; Surgeon to the Gynecean Hospital, Philadelphia. With 225 Illustrations. Fifth Edition revised. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

Most text-books have a faculty of growing larger with each successive edition, till finally, by sheer weight they fall out of the niche which they formerly occupied, and for which they were originally intended. The fifth edition of Penrose's admirable text-book is a notable exception to this tendency; for, while thoroughly up to date, it contains only twenty pages more than the first edition did. Among the features introduced during the seven years which have elapsed since its first appearance, will be found paragraphs on kraurosis vulvæ, adhesions of the clitoris, atresia of the vagina, senile endometritis, syncytioma malignum, adenomyoma of the uterus, ovarian pregnancy, myoma of the ovary, stricture of the urethra, and abdominal myomectomy; the chapters on menstruation and the menopause have been enlarged. To the student or general practitioner in need of a good book, free from fads and theories, giving rational and modern methods of treatment, well written and illustrated, this volume can be recommended.

The Practical Application of the Röntgen Rays in Therapeutics and Diagnosis. By William Allen Pusey, A.M., M.D., Professor of Dermatology in the University of Illinois; Member of the American Dermatological Association; and Eugene Wilson Caldwell, B.S., Director of the Edward N. Gibbs X-Ray Laboratory, University and Bellevue Hospital Medical College, New York; member of the Röntgen Society of London; Associate Member of the American Institute of Electrical Engineers. Second Edition. Thoroughly Revised and Enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

Although the literature upon the therapeutic use of *x*-rays during 1903 has been enormous, little that is novel has appeared. Nevertheless, such advances as have been made are recorded here. In this edition the author, as he states in the preface, has not changed in any important particular his former statements concerning either the therapeutic indications for the application of *x*-rays or the general conclusions as to their field of usefulness. To the original reports of his own cases, have been added notes giving the subsequent histories for the last year. The great weight and bulk of the volume are serious drawbacks, and in the interest of the reader are to be condemned. With only 700 pages it ought not to be more than one-half its present weight and thickness.

A Handbook of Pathological Anatomy and Histology. With an Introductory Section on Post-Mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., Emeritus Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York; and T. Mitchell Prudden, M.D., LL.D., Professor of Pathology and Director of the Department of Pathology, College of Physicians and Surgeons, Columbia University, New York. Seventh Edition, with 13 full-page plates and 545 illustrations in the text in black and colors. New York: William Wood and Company, 1904.

Delafield and Prudden's Pathological Anatomy and Histology is so well and favorably known that it is almost unnecessary to do more than announce the appearance of a new—seventh—edition. This is not a reprint of the previous edition, but an actual revision of the entire work, and a re-writing of several portions. Among the new features are the sections on immunity, Ehrlich's side-chain hypothesis, and cytolysis; the sections on the blood, malaria, and the nervous system have been brought up to date; the references to the bibliography have been increased; and there are many new illustrations, both photographs and drawings, all up to the level of the highest standard. The plates on the hæmatozoa of malaria, the blood, and lesions of the ganglion cells are particularly fine. The book well sustains the high and authoritative position acquired by the earlier editions.

A Text-Book of Materia Medica, Including Laboratory Exercises in the Histologic and Chemic Examination of Drugs. For Pharmaceutic and Medical Schools and for Home Study. By Robert A. Hatcher, Ph.G., M.D. Instructor in Pharmacology, Cornell University Medical School, New York; Formerly Professor of Materia Medica and Vegetable Histology, Cleveland School of Pharmacy; and Demonstrator of Pharmacology, Western Reserve University; and Torald Sollmann, M.D., Associate Professor of Pharmacology and Materia Medica in the Medical Department of Western Reserve University, Cleveland, Ohio. Illustrated. Philadelphia, New York, London: W. B. Saunders and Company, 1904.

This book is a laboratory manual, and is intended to place the teaching of Materia Medica on a rational basis. Instead of the dry descriptions given in the average text-book, it is suggested that the student study the specimen in the laboratory; and this little book will serve as a guide to the worker along these lines. It represents the experience of the writers in the Cleveland School of Pharmacy; and they say that the results were gratifying from the start, as the student not only showed a greater interest, but also obtained a much better grasp of the subject. The book is divided into three parts dealing respectively with the gross study of the crude drugs, their microscopical examination, and chemical exercises in Materia Medica. An appendix containing reagents, staining fluids, table of doses, and a glossary and an index complete the volume.

The Elements of Kellgren's Manual Treatment. By Edgar F. Cyriax, M.D., Edinburgh, 1901: Gymnastic Director, Stockholm, 1899. New York: William Wood & Company, 1904.

The text of this valuable book, as the author says in his preface, is founded upon the thesis which he wrote in 1901, and which was accepted with commendation by the University of Edinburgh, gaining for the writer the degree of M.D. Since that time the original thesis has undergone considerable expansion. The first part has been essentially rewritten. In the second part are included the details of many cases which have come under the author's treatment in the last few years. The subject matter is arranged in two parts, which are again divided into chapters. "Gymnastic Movements" are treated in great detail in the first part, while the second part deals with the application of gymnastic treatment to the various diseases. This subject is elaborately treated. This is the first time that a systematic, detailed description of Kellgren's Manual Treatment has been attempted. In the introduction the author gives a brief history of this system. Kellgren improved many of the movements already existing in Ling's system, and added some new ones, but he never attempted to publish anything concerning his work. Among the new manipulations were nerve frictions and vibrations, by which Kellgren treated diseases of the central nervous system with great success, and which he used to combat the acute specific infectious diseases. The method presented in this book shows a distinct improvement over all others, and is applied to many cases that have never before been touched by gymnastic treatment. The author calls attention to the fact that some of the changes made by Kellgren are often apparently slight, but it is just such changes that often make a vast difference in actual practice and greatly increase the beneficial effects of the treatment. This volume, which represents infinite labor, deserves the careful acknowledgement and encouragement of all physicians.

Clinical Urinology. By Alfred C. Croftan, Professor of Medicine, Chicago Post Graduate Medical College and Hospital; Physician-in-Chief to St. Luke's Hospital. Illustrated. New York: William Wood & Company, 1904.

Dr. Croftan's book, in the arrangement of its subject and in the treatment of its theme, differs greatly from other manuals on uranalysis. It is a study of the urine from the viewpoint of the physiologist, the student of metabolism, and the clinician, rather than those of the chemist and the microscopist. The range of topics discussed includes those usually considered in works on the urine, with the addition of chapters on the functional examination of the kidneys, including the freezing-point method, the methylene-blue test, etc. What especially distinguishes the book is the stamp of modernity, so lacking in some others of its class, which appears on every page. Old moss-grown theories are swept aside, and the reader is given a résumé of the latest researches on each question, together with a clear statement of the present status of our knowledge, and here and there a forecast of the directions in which this knowledge will advance.

In the chapter on albumin, the subject of non-nephritic albuminuria is fully discussed from the modern viewpoint. The chapters on the purin bodies, uric acid, urea, nitrogen, etc., are especially valuable on account of the author's personal contributions to these subjects. The whole structure of fact and theory in connection with the purin bodies has been exposed in these pages and the relation of these substances to disease carefully explained, according to up-to-date views. Ruhemann's method of estimating uric acid is not mentioned, nor are the method of Camerer and the purinometer of Hall described,—omissions which conflict with the author's avowed aim to give brief clinical methods wherever possible, even though they be not absolutely accurate. Doremus' well-known apparatus for urea is mentioned only to be condemned, and the author prefers the less well-known instrument of Hufner.

The chapter on carbohydrates is alone worth the purchase of the book. It is full of the most suggestive material and the discussion of glycosuria, brief as it is, presents the subject in an admirable manner. In the section on inorganic constituents a departure is made from old models by a much fuller and deeper discussion of the metabolic relations of these bodies.

Hyaline casts, according to the author, always indicate a functional disorder of the kidneys, which may be transient, but are to be regarded with suspicion, as they indicate the beginning of a renal inflammation. In view of the fact that hyaline casts are found in almost every urine, these conclusions are somewhat at variance with the modern trend of opinion, which considers pure hyaline casts as of very slight import. A great deal of scepticism is expressed by the author as to the possibility of differentiating epithelia from various parts of the urinary tract, and he gives no guide to the localization of affections of the various organs of this system by means of the microscope, though he figures the different epithelia diagrammatically. In the final chapter on the determination of the renal function, the author gives a brief outline of the subject, together with a very conservative estimate of the value of the various tests now employed for this purpose.

Dr. Croftan's book will delight the advanced student and the broadly educated "all-around man" of medicine. It will be found useful by the scientific practitioner and the specialist on diseases of metabolism.

Society Reports.

THE SEVENTY-SIXTH CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

Held at Breslau, September 18-24, 1904.

(Special Report to the MEDICAL RECORD.)

For the third time Breslau welcomes this society and offers its generous hospitality to a Congress of the German Naturalists and Physicians. The quaint older quarters as well as the broad avenues of the new town are gaily decked, and everywhere flags fly in salutation to the visitors. Two thousand guests were present on the opening day, and the streets were filled with professorial dignitaries whose gray beards wagged merrily in animated conversation with old acquaintances. The Congress convened in the City Theater and the session was formally opened by addresses from the President of the Province, the Dean of the University, the Mayor, and the heads of the learned societies.

The Mechanics of Development, a New Branch of Biological Science.—Professor WILLIAM ROUX of Halle presented a communication with this title. The earlier investigators of development were content with merely descriptive lore and were slow to progress, but when William His began his efforts to discover the origin of every perfected organ in its ancestral cleavage cell, the horizon was greatly broadened. But only a study of the causative agencies themselves can fully illuminate the subject, and in this way the new conception of the mechanism of development came into being. Experiments on the frog show that, all extraneous influences being excluded, the line of division of the first cleavage cell of the ovum always indicates the line of symmetry of the future animal, so that the position of head and tail is immediately determined. All parts of the ovum are not essential for full development, for partially emptied frog's eggs develop into complete embryos. It is possible to limit development to a single half and thus to produce half-embryos consisting only of the anterior, posterior or lateral portion. Many observations of different authors have brought to light numerous other factors, such as the superficial tension and osmotic pressure of the first cleavage. These factors would justify the establishment of a purely mechanical theory if other experiments had not revealed the fact of self-regulation, as shown by the regeneration of lost members and by functional adaptation. The following conclusion is the result of many observations; when the first cleavage cell becomes round again after the division, a complete embryo will result; if it remains hemispherical only a half embryo is found. In the author's opinion, both the typically mechanical, and the regulatory laws are subordinate to the causative doctrine, and this will be the chief objective point for scientific research.

The German Expedition on the Gauss.—Dr. HANS GAZERT of Berlin described this voyage, which was undertaken with the idea of advancing as far south as possible and then wintering at some point for the purpose of scientific observation. On the twenty-first of February, 1902, the newly-discovered Emperor William I. Land was reached, and winter quarters were established on the ice fields 30° beyond the Antarctic Circle. For five months storms and snow prevented excursions from the ship, and the monotony and inaction caused mental depression among the members of the expedition, though neither insanity nor scurvy developed. Canned foods, preserves, fresh meat of seals and penguins, as well as alcohol, formed suitable provisions and kept them well. Wounds healed without suppuration, but very slowly; the hair, beard and nails grew only very slowly, and catarrh never occurred. Several new facts were discovered, including investigations on the plankton, and the observation that south of 63° east winds prevail. The sea water was very poor in germs, though these were present in abundance in the kitchen refuse in spite of the low temperature. A sledge expedition penetrated further south, and on the Gaussberg four months of scientific work was done. Below the ice the ground was composed of gneiss and granite. The prevailing dryness was a noteworthy feature. The highly satisfactory opportunities for scientific work made attempts to penetrate further south seem ill-advised, so this idea was abandoned. On the thirty-first of January, 1903, the first crevasse formed, and on February eighth the ice began to move. It was found impracticable to carry out the original intention of spending a second winter further to the westward, and the scientific workers left behind on Kerguelenland, one of whom (Dr. Euxensperger) had died, were picked up, and the voyage homeward begun. The author deprecated the criticisms to which the expedition had been subjected, and said its object had been scientific discovery and not the pursuit of danger, and that in this respect it had been very successful. Numerous photographs illustrated the paper.

The Frequency of Tuberculosis in Man.—Dr. KRÄMER read this first paper in the Section of Internal Medicine. The doctrine of the universal prevalence of tuberculosis is still unproven, for the high autopsy statistics of hospitals are based upon the poorer population, the lesions ascribed to tuberculosis, such as calcareous deposits, may sometimes be due to other causes, and the large number of inactive latent cases must be deducted, so that only 30 per cent. of infections remain.

Dr. FREYMUTH of Breslau gave seventeen patients tuberculin in pill form and obtained valuable results. Cases giving only a slight reaction on internal administration become very susceptible to later injections, and very small doses then suffice.

Dr. MOURNEY of Mettmann obtained unequal results with tuberculin injections, and believes that it is largely a question of the powers of immunity of the patient, and that these may be stimulated by the tuberculin.

The Prognostic Significance of the Pulse in Pulmonary Tuberculosis.—Dr. SCHNEIDER of Göbersdorf read a paper on this subject, saying that acceleration of the pulse always indicated injury to the patient. He considered pulses up to 90 normal, from 90 to 110 accelerated, and above this, much accelerated. In all stages of the disease patients with normal pulses are able to continue at work longer and to live longer than others. This fact is therefore of importance in considering the question of sanatorium treatment.

Dr. WASSERMANN of Meran called attention to the necessity for a well-regulated circulation in tuberculosis, and described a gymnastic treatment he employed.

Dr. STRÜMPELL of Breslau chairman of the section, summarized the results of the discussion by saying that the tuberculin treatment is the stage of development, and that it has a promising future.

Artificial Feeding of Infants.—Dr. SCHLOSSMANN of Dresden opened a discussion on this subject. Milk used in place of breast milk must be pure, good and fresh, and should come from cows that go out to pasture. As the observation of these conditions makes the price of milk high, the municipal authorities should become milk producers or should control the dairies, and should offer facilities for instructing the mothers of children, especially pointing out the advantages of breast milk. The poor should receive milk gratis. Canned milk preparations are not suitable for infant feeding. Behring's statement that boiled milk is injurious is not justified, though the milk should not contain many germs even before boiling. The addition of formalin as suggested by Behring checks the lactic acid formation but not the growth of other germs, and this agent is injurious to infants even in minute quantities.

Dr. SEIFFERT of Leipsic reported some interesting experiments on new-born calves. Boiled cow's milk can cause profuse diarrhœa, but if the animals have previously been given colostrum they remain well. The colostrum

produces a passive immunity in the child, which later becomes an active immunity. The addition of such substances as formaldehyde or peroxide of hydrogen, etc., is injurious. In the protracted discussion which followed Heubner and others condemned the preserved milks and spoke of the presence of streptococci in milk as being especially dangerous.

Drainage in Empyema.—Dr. RAUCHFUSS of St. Petersburg demonstrated illustrations showing triangular drainage openings on the healthy side in empyema, these reaching to the vertebral column as a consequence of the pushing of the entire mediastium to the healthy side.

PFAUNDLER, of Graz, showed an apparatus intended to announce a movement of the bowels in an infant by means of an electric bell. The apparatus can be arranged so as to give the child an electric shock, and is well adapted for use in cases of nocturnal enuresis.

Bactericidal Action of Radium.—Dr. ARCHKINAS opened a discussion on this subject in the section on Dermatology. He said that three varieties of radium rays, α β and γ might be distinguished. The γ rays which are not influenced by the magnetic field possess no bactericidal powers. The α rays and β rays which are deflected to different sides by the magnetic field, kill bacteria after some time.

Dr. HOLZKNECHT of Vienna spoke of the nature of ray therapeutics. How is it that rays differing so much in nature as the Röntgen, radium, cathode and sunlight rays should act on the photographic plate and on living tissues in so similar a way? Goldstein's hypothesis is correct, viz. that all these rays as soon as they strike ponderable matter become converted into ultraviolet rays. The elective action of the rays is only relative, that is, all tissues are injured by the rays, but to a different degree. Holzknecht has employed radium spread in a thin layer over a surface in order to treat more extensive cutaneous areas in a short time. For the mouth and nose suitably shaped applicators have been made. In the discussion the author's views regarding the ultraviolet theory were not corroborated, though all the speakers coincided with his theory of elective action.

Diagnosis and Treatment of Gonorrhœa.—Dr. ALEXANDER of Breslau spoke of a new agent for the diagnosis and treatment of gonorrhœa. He injects a 1 per cent. solution of peroxide of hydrogen into the urethra after the gonococci can no longer be demonstrated. The resulting secretion often shows the organism again. The author assumes that the foam formed opens the choked-up glands and renders them susceptible to treatment with bactericidal injections.

Dr. POSNER of Berlin said that he had often found the nuclei of the cells in urethral pus degenerated into angular, deeply-staining masses, and that this was characteristic of chronic non-gonorrhœal urethritis. Marked vacuolization of the leucocytes observed on the second day of the discharge points to a rapid subsidence of the process. Large numbers of mononuclear cells do not, as Poppenheim states, indicate a cure, but also frequently occur in the third to fifth week of gonorrhœa.

The Action of Physical Therapeutics in Inflammation.—Dr. SCHÄFER of Breslau read a paper on this subject. He drew threads infected with bacteria under the skin of the backs of rabbits, and then treated one side with heat, ice, and wet dressings, using the other side as a control. Continuous heat was most efficient; the ice-bag was also serviceable, especially when a pig's bladder was used as container. The wet dressing covered with gutta percha was also useful, but not the Priessnitz compress. These statements were illustrated by anatomical preparations.

In the Gynecological Section a discussion relative to the method of treating carcinoma of the uterus resulted in the conclusion that the abdominal operation was preferable. Mackenrodt counseled complete clearing out of the pelvis.

Intrauterine Menstruation.—Dr. HALBAU of Vienna spoke on this topic. His observations afforded an explanation of the cases of bleeding from the genitalia sometimes observed at the birth of female children. This is due to what is undoubtedly a menstrual process.

The Mechanism of Labor.—Dr. SELLHEIM of Freiburg read a very interesting paper on this subject. By forcing a fœtus through a tubular model he showed that the fœtus must carry out the normal mechanism of labor, following the laws of least resistance.

In the Surgical Section Hoffa spoke enthusiastically of models seen in America for the treatment of spondylitis. V. Mikulicz praised the skill of American surgeons, particularly that of Young, in his report of eleven cases of prostatic hypertrophy that he had operated perineally by means of Young's instruments. He makes a median incision, and with one index finger in the rectum, bluntly dissects down to the gland with the other index, and after incising the capsule, turns out the gland. All the cases healed well and gave good results.

Nerve Blocking in Neuralgia.—Dr. HEILE of Breslau reported upon a method of treatment of trigeminal neuralgia employed in v. Mikulicz's clinic, and which gives results almost equal to those attending extirpation of the nerve. A weak cocaine-adrenalin solution, followed by a 1 per cent. solution of osmic acid, is injected with a Pravaz syringe into the foramen of exit of one of the three nerves, according to the localization of the disease. The openings are easy to strike, and the fact that they have been found is shown by a sudden sinking in of the needle. Out of twelve cases so treated nine gave excellent results, and an advantage of the method lies in the fact that the injection may be repeated as often as desired.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 6, 1904.

ANDREW H. SMITH, M.D., IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Obstetrics and Gynecology.

The After-Effects of Hysterectomy on the Nervous System.—Dr. GRAEME M. HAMMOND said that the brain was the only part of the entire nervous system which seemed to be influenced by operations upon the pelvic organs; the peripheral nerves and cells in the cord remained apparently unchanged so far as primary degenerations are concerned, even after the lapse of years. But so much cannot be said of the brain. Among the sequelæ of hysterectomies he mentioned certain psychoses, paranoia, involutional insanities, melancholia, presenile and delusional insanities. Epilepsy, hysteroepilepsy, and hysteria, and occasionally profound neurasthenias may follow. It cannot be claimed that the extirpation of the uterus is ever in itself a cause of psychoses or neuroses; when paranoia develops it is not because of the removal of the uterus, or because it ceases to perform its function, but because the individual was born with a tendency to become a paranoiac. These conditions may exist when we have profound nutritional changes at the menopause; just so may they occur when the uterus is removed. When epilepsy, hysteroepilepsy, or hysteria follows a hysterectomy it is because the subject was neurotic, or had become neurotic from long-continued illness. Dr. Hammond wished to be distinctly understood as believing that hysterectomy causes *per se* no mental or nervous diseases which other operations would not cause. That extirpation of the uterus and ovaries might be followed by mental and nervous diseases there was no doubt. The attempt had been made to prove that the ovaries secreted some substances which were necessary for the integrity of the nervous system, but this could not be proved. It should be remembered that the diseases which call for such a radical procedure are severe in character and exhaust the brain cells, and makes it difficult for such patients to stand the shock of such

operations. Therefore the surgeon should carefully consider the question of certain nervous symptoms following hysterectomy, as well as other operations. He concluded as follows: (1) There are no mental or nervous diseases which develop as the result of hysterectomies or ovariotomies *per se*. (2) The loss of the uterus and ovaries and the sudden cessation of menstruation have nothing to do with the development of mental or nervous diseases. (3) The shock of the operation is the sole exciting cause of the nervous diseases which follow hysterectomy. But shock alone is not sufficient as a cause; there must be some congenital defective brain, or congenital tendency to premature degeneration, or an acquired neurosis which must exist at the time of the operation.

The After-Effects of Hysterectomy upon the General Health.—Dr. Eugene Coleman Savidge said that at Roosevelt Hospital it had been his fortune to come in contact with many patients whose uteri and ovaries had been removed; most of them had been recent cases. The conviction, as a result of his observations, grew upon him that ovarian tissue was necessary and essential for the woman's well being. Among the after-effects of hysterectomy might be mentioned the lusterless eye, the roughened voice, the increased growth of hair, the increased amount of fat, the devitalization or defeminization of the individual, the change from the alertness of city life to that of the country dullness, the wiping out of zest and the lack of pride, the abolishment of the feminine element, etc. The quality of hope is often removed after hysterectomy.

The After-Effects of Hysterectomy on the Sexual Functions.—Dr. Hiram N. Vineberg said that the whole subject of the sexual functions in women was very vague and women were seldom interrogated regarding this point. In his opinion it had little bearing upon the conditions for which women sought advice. Some women with no sexual desire have large families, and the reverse is also true. Dr. Vineberg then considered the question of the seat of the sexual instinct in women. The removal of the uterus and adnexa had little influence upon the sexual instinct; this statement was based upon his own investigations and from a study of the reports from other writers. He had recently written to several of his patients upon whom he had operated, and many stated that there had been no effect upon their sexual passions. Some even stated that prior to operation they never knew what passion was; following hysterectomy it developed to a marked degree. In no instances did the sexual appetite become less than what it was prior to operation. In no instances was the sexual appetite destroyed. He concluded that whatever effects the removal of the uterus and ovaries might have upon the woman, it had little or none at all upon the sexual feeling.

Dr. Edwin B. Cragin said that in such a discussion one should look upon the after-effects as those of comparison, the comparison lying not between the absence of a normal uterus and presence of a normal uterus, but between the absence of the uterus and presence of a diseased uterus. The after-effects were going to depend upon what condition the uterus was in and the symptoms from which the patient suffered. He believed that one should draw a sharp line between the after-effects following the removal of the uterus and ovaries and the removal of the uterus alone, because the effects produced were distinctly different. He could not endorse all that Dr. Hammond had stated; in his own experience the effect of removing the uterus and appendages had been determined by the amount of shock produced, just as from an operation upon an extremity; but the same amount of shock and gravity of operation in any other part of the body did not produce the same amount of disturbance of the nervous system as operation upon the uterus and appendages. With regard to the effect upon the general health he called Dr. Savidge's attention to the fact that when he (Dr. Savidge) was in the Roosevelt Dispensary it was the custom to remove both ovaries with the uterus; therefore, most of the hysterectomies then done were panhysterectomies, and not the removal of the uterus and leaving of one or both ovaries, as the custom is at the present time. The removal of both ovaries left the woman in a neurotic condition, which was worse than the disease for which the operation was performed in many instances. To-day the pendulum had swung the opposite way, and some ovarian tissue was left whenever possible. Another division must be made in considering the after-effects of hysterectomy and depended upon whether the cervix was removed with the uterus or not. He admitted that the sexual feeling may not be greatly altered in a large majority of the cases, but it did make a difference in the conditions of the vagina; for instance, sometimes vaginismus was very marked and resulted from the rapid atrophy which sometimes followed this operation. Provided the ovaries and cervix be left the sexual life of the woman, so far as satisfaction in sexual intercourse was concerned, was not changed. It had been his experience in several cases when both ovaries had been removed that there was such a change in the external genitals, such as atrophy, that sexual intercourse had to be abandoned. This was an exception to the rule, and yet that was one of the results.

Dr. J. Riddle Goffe said that in the removal of an important part of any individual, shock, which was usually only a passing incidental experience, might at times be of such a character as to affect the mental characteristics for the balance of life. The self-consciousness of disfigurement or mutilation often restricted business and social relations, so that the entire morale might be changed. Such effects might naturally be expected in the removal of so important an organ as the uterus, and such results sometimes, though very rarely, occurred. The functions of the uterus being intimately connected, not only with the nervous system, but also with the psychological equilibrium of the woman, have been said to dominate her life. Certain it is, that the function of reproduction exerts such a reciprocal influence upon the traits and characteristics of the individual as to markedly distinguish the parous from the multiparous woman. The woman subjected to hysterectomy was deprived of the experience of motherhood, and to that degree her moral, mental, and emotional horizon was limited. Many women, however, have experienced this broadening influence before the operation had been performed, so that it was necessary to classify according to age and previous condition. From the standpoint of the woman there were three aspects in which this question would be considered: (1) The effect upon the sexual appetite and enjoyment. At the meeting of the American Gynecological Society, 1903, where this question was discussed, it seemed to be the consensus of opinion that the ovary was the determining factor in the sexual sense. The removal of the uterus had absolutely nothing to do with it. Dr. Goffe's experience led him positively to confirm this opinion, although it had been the experience of Dr. Noble, who had made a special study of this matter, that the removal of the ovaries did not affect the sexual appetite any sooner than would happen in the natural course of events. (2) What will be the effect of the suppression of ovulation and menstruation? These phenomena are regulated by three factors, the uterus, the ovary, and nerve centers. When both these organs are removed the symptoms of menopause appear, as well as abnormal psychic manifestations, but the system gradually adapts itself to the changed conditions. If the general health had been depressed, it usually happened that general nutrition was improved and that there was a gradual restoration to a normal, healthy condition. The state of the general health after this operation was the true test of the success of the procedure. He said that the results of his work in the large majority of cases had stood this crucial test. (3) How will the nervous system functionate under the new order? When the uterus only had been removed and the ovaries left, menstruation

had ceased, but the nervous manifestations had been largely absent. He emphasized the point that whenever possible at least one ovary, or as much of it as was healthy, should be left *in situ*. It had been the experience of Dr. Lindley that hysterectomy cases recovered more promptly when the ovaries were left, and he knew a number of women, holding responsible positions, upon whom hysterectomy had been performed, who were having the brightest and most successful years of their lives.

Dr. W. Gill Wylie did not agree with the statement that the removal of the uterus and adnexa had no effect upon the nervous system. In many instances there was a marked depression, and even melancholia, following such operations. To-day he would not remove all the ovarian tissue in any woman under 45 years of age if it were possible to save any portion of it. The younger the woman the less willing was he to remove all the ovarian tissue. In young women the changes that took place were very marked, especially when they were under 30 years of age; there was a rapid atrophy, and sometimes the changes in the tissues became pathological, in many cases giving rise to vaginismus. This occurred especially in the young. He said he was satisfied that it was not a dangerous procedure to leave the ovaries, or parts of the ovaries in doing hysterectomy. The most important tissue to remove in order to get permanent results was the Fallopian tube, especially its mucous lining.

Dr. F. H. Wiggin said it had never been his custom to remove normal tissue, and that he believed in leaving in the cervix whenever it was possible.

Dr. Graeme M. Hammond said that the minds of the gynecologists seemed to be imbued with the idea that the integrity of the nervous system depended upon the integrity of the ovaries. This was not true. He believed that women might have perfect, healthy minds and nervous systems without uterus or ovaries; they might be removed without any injury to the nervous system whatever. On the other hand, trivial operations on the uterus and adnexa are often followed by profound mental symptoms.

Dr. Hiram N. Vineberg said that in looking over the literature he noted the belief that sexual passion ceased at the menopause was not so common as generally supposed, and there had been reported cases in which this passion continued until advanced age. He could not take a positive stand in reference to the advantage of leaving in the cervix and portions of the ovary and the influence upon the future welfare of the patient; that was a subject still *sub judice*. In the majority of cases when the uterus has been removed the ovary will atrophy in a short time.

Before the adjournment the president introduced Prof. T. Clifford Allbutt of Cambridge, one of the Honorary Members of the Academy.

Cincinnati Academy of Medicine.

At a regular meeting, May 9, Dr. Samuel Iglauer read a paper on "Nitrous-oxide Ether Anæsthesia." He first compared ether and chloroform, showing that chloroform was by far the more pleasant to take, but as shown by Hewitt's statistics of over 1,000,000 cases, was also much more dangerous; one death resulting in every 3,162 chloroform cases, and one in 10,302 ether cases. The zone between the psysiological and the lethal dose of chloroform is much narrower than that of ether, and the failure comes much more suddenly with chloroform, ether giving plenty of warning. The advocates of chloroform claim that the after-effects of ether are worse than those of chloroform and that pneumonia is much more frequent, but Drummond has noted the relation between painful abdominal wounds with limited diaphragmatic action and pneumonia, and Mikulicz shows that the pneumonia is caused more by the operation than the anæsthetic, and gives tables showing that he has had more pneumonias following operations under cocaine than in the same operations under general anæsthesia. It is stated that ether causes more trouble in the kidneys, but experimentally fatty degeneration has been produced by long-continued chloroform anæsthesia, not only in the kidneys, but in the liver and the heart itself, while ether has failed to produce these results. Ether produces less vomiting because it is more volatile and passes off more quickly. This also explains why nitrous oxide, ethyl-bromide and ethyl-chloride so seldom produce this symptom. Ether then, being the safer anæsthetic, should be made as agreeable as possible by relieving the irritating throat symptoms and sense of suffocation, and reducing the stage of excitement to a minimum. This was done by Clover in 1876, when he devised his apparatus for administering gas followed by ether. Nitrous oxide is the safest anæsthetic known, its mortality being one in 750,000 cases, and its administration is not unpleasant. When followed by ether, the patient passes directly from one to the other without excitement. The writer here presented his apparatus for the gas-ether sequence. It consists of a metal face-piece containing a wire basket for gauze; above is a glass ether container with a stop-cock. Accurate fitting of the face-piece is obtained by a rubber cushion. The face-piece is joined to a rubber bag for the gas by a piece of metal tubing; a lever projects through an air-slit in this tube and is connected with an obturator, which controls the escape of the gas. On each side of the face-piece is a trap for admitting air, if desired. In using, the basket is filled with gauze and the container with ether; the rubber bag is then filled with gas (about 2 gals.). The air-slit is opened, and after a few breaths of air, to inspire confidence, the gas is turned on, which at the same time closes the air-slot. The patient then breathes the gas back and forth into the bag; after about 40 seconds he will show slight cyanosis and stertor, and the cornea will become insensitive. Then the ether is turned on, about 5i being allowed to flow onto the gauze. He now breathes a mixture. In about one minute, or if stertor becomes marked, allow a breath of air, and then continue to feed the ether slowly. In about three minutes complete ether anæsthesia ensues. The large gas bag is then removed and replaced by a lighter rubber bag. The administration is then continued, enough air being admitted to prevent cyanosis.

The speaker said he had notes of sixty-two cases in which his apparatus was used in major and minor operations. Of these, only three required restraint while being anæsthetized, and two of these were alcoholics. These patients varied in age from four to seventy-three years. Vomiting occurred only twice during the anæsthesia; thirteen patients became cyanosed. Special advantages of the gas-ether sequence are: (1) The two safest anæsthetics known are used. (2) The method can be used as a routine for nearly any class of operations. (3) Unconsciousness is quick and leaves no unpleasant recollections. (4) Struggling, excitement, choking, and the initial vomiting are eliminated. (5) Nitrous oxide does away with the large amount of ether required to induce anæsthesia. (6) Only one-third to one-half the ether is used in the close, as compared with the open, method. (7) The patient breathing the same warmed ether to and fro suffers less from refrigeration. (8) The atmosphere of the room is not saturated with ether fumes. (9) Deep anæsthesia is more easily maintained. (10) The method can readily be changed from the close to the open by removing the bag. (11) In clinical work, the patient can be anæsthetized when the operator is ready, and need not be put under in advance and kept waiting. (12) Recovery from narcosis is more rapid. (13) Nausea, vomiting, and headache are less intense after operation. (14) It is a time-tried method and is recommended by leading anæsthetists.

At a regular meeting, May 20, Dr. Wm. F. Jelke reported the following obstetrical case: A woman of neurotic type, the mother of four children, who had had two miscarriages between the fourth and fifth month, after the second miscarriage, had hysterical attacks, with partial loss of consciousness. Her second child had epileptoid attacks until six years of age. Four weeks before recent confine-

ment she fell downstairs, spraining her ankle and striking right side of abdomen on step. Labor pains, with slight hemorrhage, followed, and os dilated to admit finger. She was given morphine hypodermically and placed in the Trendelenburg position. A pillow under the head relieved tension on abdominal muscles. Warm applications were applied locally to relieve bruising, and after six hours labor pains ceased. On May 23, one week before this report, labor pains came on. The position was found to be left occipito-posterior. The os was dilated, the membranes very tough and unruptured, while the amniotic fluid was much diminished. After two hours, membranes having been cut, the head was rotated with forceps and delivered. The child was blue and heart not palpable. The cord was quickly cut, and the usual method failing, the lungs were inflated by a bicycle pump through a catheter passed into the larynx; warm towels were applied and the skin irritated at frequent intervals by massage with camphorated oil. Respiration was restored about one hour after birth. That evening the child began to have convulsions, beginning in the mouth and eyes and becoming general. These occurred about every hour and were preceded by a sharp cry. The next evening the rectum was washed out and 3 grains of chloral hydrate were injected in ℥ii of Pasteurized milk and ℥i of salt solution. This was followed by a hypodermic of salt solution with 4 drops of whiskey, which was repeated some hours later with 5 drops and again with 6 drops. The general condition of the child improved on the taking of the salt solution, and only two more convulsions occurred. On the third day the child took some milk which had been drawn by the breast pump, and on the fifth day nursed for itself. Following the convulsions it remained spastic for some days, but this has disappeared and improvement continues.

Dr. Kennon Dunham presented Dr. Sweet's apparatus for localizing a foreign body by means of the *x*-ray.

Philadelphia County Medical Society.

At a stated meeting, held May 25, Dr. Chas. W. Burr exhibited "A Case of Osteoma of the Frontal Bone." The patient was a colored lad, perhaps twelve years old, with a family history of syphilis, who seven years previously had been kicked in the frontal region by a horse. A swelling soon appeared in the situation of the injury, and gradually increased in size until it had attained quite considerable proportions. At the same time vertigo, headache, and static and motor ataxia developed and became marked. There was also impairment of hearing. A skiagram showed the frontal bone to be greatly enlarged from the presence of hyperostosis or exostosis and exerting pressure on the brain and on one eye. The knee-jerk was preserved on one side and absent on the other. The eye-grounds exhibited no lesion. Improvement in all of the symptoms took place under antisyphilitic treatment.

Dr. J. Madison Taylor read a paper entitled "Special Lectures for the County Medical Society; a Suggestion." He proposed the establishment by the County Medical Societies of large cities of post-graduate lectures, to be given on certain evenings set apart for the purpose, by members of the Society or others, illustrated by means of blackboard or other drawings or lantern demonstrations.

Dr. Chas. K. Mills read a paper entitled "A Glance at the History of Cerebral Localization, With Some Considerations Regarding the Subdivisions of the Areas of Representation of Cutaneous and Muscular Sensibility and of Concrete Concepts." He traced the evolution of cerebral localization from its uncertain and remote beginnings down to its present comparatively refined development, giving especial credit among early investigators to Gall, and among more recent students of the subject to Fritz, Hitzig, Flechsig, Ferrier, Horsley, Beevor, Sherrington, and Grünbaum. The advances in this department of knowledge have been made partly from clinical and pathological observations on man and partly from experimental observations on animals. There is reason for believing that the motor centers for the different parts of the body are situated in front of the central fissure, and the sensory centers are situated behind this fissure, and that there is a certain correspondence or relationship between the situation of the two sets of centers in the cerebral cortex, with reference to the respective parts of the body. It would seem that there are, further, special centers for abstract and concrete concepts, the one being situated in the frontal region and the other in the upper and lower parts of the posterior portion of the brain. The occipital lobe contains an object-seeing center, and the temporal lobe a center for musical apperception.

In the discussion, which was participated in by Drs. Francis X. Dercum, Wm. G. Spiller, Chas. W. Burr, Wm. Pickett, G. E. de Schweinitz, Chas. H. Frazier and E. W. Holmes, various phases of the subject were dwelt upon and a full measure of praise was accorded Dr. Mills for his long-continued studies and his valuable contributions in this field of inquiry.

Medical Society of City Hospital Alumni, St. Louis.

At the meeting held May 26, Dr. S. E. Solley, of Colorado Springs, read a paper on "Climatology." Dr. Solley said he wanted to call attention to the importance of this subject rather than give an epitome of what climatology is. Climatology has received a set-back by the late discoveries of the value of hygiene in the treatment of tuberculosis. Altitude is a very powerful remedy, but for patients who have lived on the coast it is a severe change. Speaking of his personal experience, he said that in Colorado they used to be flooded with cases sent there too late, and the patients were not instructed to follow any particular way of living, so that local physicians had very little control over them. Hygiene is the first essential, and a bad climate with good care is better than a good climate without care. To secure the highest degree of benefit from sun-heat, dryness is necessary; therefore, a sunny and dry climate is of great value. No climate is suitable to all cases, and to know about a climate it is necessary to know about its meteorology as well as its topography. Climatology is a science, and if the data are before the physician he can build up a climate for himself. Many other diseases than tuberculosis are benefited by a change of climate. Kidney diseases are very much benefited, and for these troubles Arizona is probably the best because it is more equable. Heart disease and chronic rheumatism are also greatly benefited. The speaker made a plea for the study of Climatology being included in the curriculum of medical colleges, even though it be a short time during the school year.

Prophylaxis Against Malaria by Quinine.—In an official report by H. Ziemann, based on his observation in the German possessions in Cameroun, Africa, the following conclusions are contained. In 16 per cent. of those who received prophylactic treatment regularly the outbreak of the fever was entirely avoided. When no prophylactic measures were employed none was spared; and when they were not followed regularly, only one. Furthermore, in those regularly under treatment 23 per cent. only experienced a slight attack, and in 25 per cent. the fever disappeared as soon as more stringent measures were adopted. The majority of those under prophylactic treatment (90 per cent.) were able to work in the tropics, of those under irregular treatment only 67 per cent., and those without treatment only 12 per cent. These results would be even better if the prophylaxis were more universally applied. The use of quinine alone, however, is not sufficient, and all the other known methods for securing hygienic conditions in the tropics are essential. Among these is the necessity of securing the coöperation of the natives by teaching them, if possible, the value of such methods, and the author reports that this has been attended with some degree of success in the locality in question.—*Archiv für Schiffs- und Tropen-Hygiene.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgement will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK FOR THE YEAR 1904. 8vo, 502 pages, muslin. Published by the Society.

A TREATISE ON OBSTETRICS FOR STUDENTS AND PRACTITIONERS. By EDWARD P. DAVIS, A.M., M.D. Second Edition. 8vo, 809 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 8, 1904:

	Cases.	Deaths.
Measles	44	3
Diphtheria and Croup	248	34
Scarlet Fever	103	6
Small Pox		1
Chicken Pox	16	
Tuberculosis	291	157
Typhoid Fever	136	26
Cerebro-Spinal Meningitis		10
Typhus Fever		
Yellow Fever		
Cholera		
Totals	838	237

Malaria on the Shores of the Black Sea.—The St. Petersburg Institute of Experimental Medicine has sent an expedition to the shores of the Black Sea to inquire into the prevalence of malaria, especially in the neighborhood of Gagory, which is a climatic health resort.—*British Medical Journal.*

The War and the Supply of Medical Men for Civilians.—Every day, says the *Novoe Vremya,* the war is thinning the ranks of the St. Petersburg medical men, and thus the remaining contingent of town medical men is overloaded with work. Measures are being taken for recruiting a temporary staff to continue on duty during the absence of the city medical practitioners.

Lepers in the Transvaal.—A recent report from Mr. George Turner, the medical officer of health for the colony, states that whereas in 1895 the number of lepers under his charge was 109, it is now over 200. It is not exactly known, however, how many leprosy afflicted people there are in the Transvaal. A medical man who had been in charge of lepers in that country asserted in 1900 that there were at least 3,000 lepers.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended October 7, 1904.

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Illinois, Chicago	Sept. 25–Oct. 1	3	1
Louisiana, New Orleans	Sept. 25–Oct. 1	1	
Massachusetts, Fitchburg	Sept. 25–Oct. 1	1	1

THE GYNECOLOGICAL IMPORTANCE OF PROLAPSED KIDNEY.*

By AUGUSTINE H. GOELET, M.D.

PROFESSOR OF GYNECOLOGY, N. Y. SCHOOL OF CLINICAL MEDICINE.

THAT prolapse of the kidney has an important bearing on gynecological conditions there can be no question; that it is often overlooked as an etiological factor both in producing and maintaining congestion of the pelvic organs and diseased conditions coincident thereto, and in producing symptoms which are referred erroneously to the pelvic organs is very true also, and is constantly observed in cases coming to me from other gynecologists.

I first expressed my views publicly on this point at the Saratoga meeting of the American Medical Association, in 1902, and my paper was published in the *Journal of the Association*, August 23 of the same year. They were received with some scepticism by some who discussed the paper and who, I hope, have gained wisdom in the light of riper experience.

In that paper I pointed out that the kidney when prolapsed overlaps the ovarian vein as it ascends along the spine, and compresses this vein, thus obstructing the return circulation from the pelvis when the waist is constricted by the corset or clothing. It is not necessary that the constriction at the waist be more than sufficient to support the clothing, for the intestinal distention, always associated with this condition, is an important factor in forcing the kidney back against the spine. It would seem that the kidney, being movable, would escape such compression. But the colon, being attached to the kidney, drags upon it when it is distended, and holds it in position at the waist line favorable for compression. The distended bowel must necessarily become displaced below the waist line, since there is no room for it above.

Even in the early stages of prolapse the kidney may retard the circulation in the ovarian vein; because when the kidney descends its lower pole swings inward towards the spine, overlapping the vein, as shown in the drawing by the dotted outline.

Compression and consequent obstruction of the circulation of the ovarian vein may be brought about in another manner by prolapse of the kidney. Bear in mind the relation of the ovarian vein to the ureter. The vein is in front and the ureter behind it, where they cross. Therefore, when the kidney descends the ureter becomes bent upon and drags on the vein.

Distention of the ureter from accumulation of urine in consequence of obstruction at the point of flexure will also cause pressure on the ovarian vein.

Thus it will be seen that prolapse of the kidney is an important element in maintaining congestion of the pelvic organs, and is to be regarded as a factor, and a very important one, in causing diseased conditions arising therefrom.

It is certainly true that in almost every woman having prolapse of the kidney there is some associated pelvic disease. The position of the kidney may not be always the sole cause, but I contend that it is an important etiological factor in these conditions, and when so, a cure is not possible without fixation of the kidney. This has been so frequently demonstrated that I am thoroughly convinced upon this point.

Prolapse of the kidney may have a strong influence in causing or maintaining such conditions as persistent leucorrhœa, endometritis, uterine hemorrhage, uterine displacements, even ovaritis and salpingitis, and hemorrhages into the pelvis (hematoma and hematocele), irritable bladder, and even cystitis.

The gynecologist in particular should hence make a special point of recognizing this condition or excluding it in making his diagnosis, and should, as a matter of routine, examine all his patients for this purpose, not once, but repeatedly if necessary, until he can be convinced of its presence or absence. Repeated examination is sometimes necessary before a positive diagnosis can be made, because the colon, when distended, is interposed between the kidney and the abdominal wall, acting like an air cushion, through which it is impossible to distinguish the kidney.

The frequency of prolapse of the kidney in women, especially gynecological patients, is another cogent reason for thus examining every female patient, and not considering the examination and diagnosis complete without it.

Prolapse of the kidney should never be overlooked in these patients, for unless it is recognized and its importance in relation to the pelvic organs is appreciated, not only will such oversight give rise to embarrassment on the part of the gynecologist when it is discovered that he has overlooked so important a condition, but he will often, in consequence of ignorance of the whole trouble, give advice that may prove harmful to his patient.

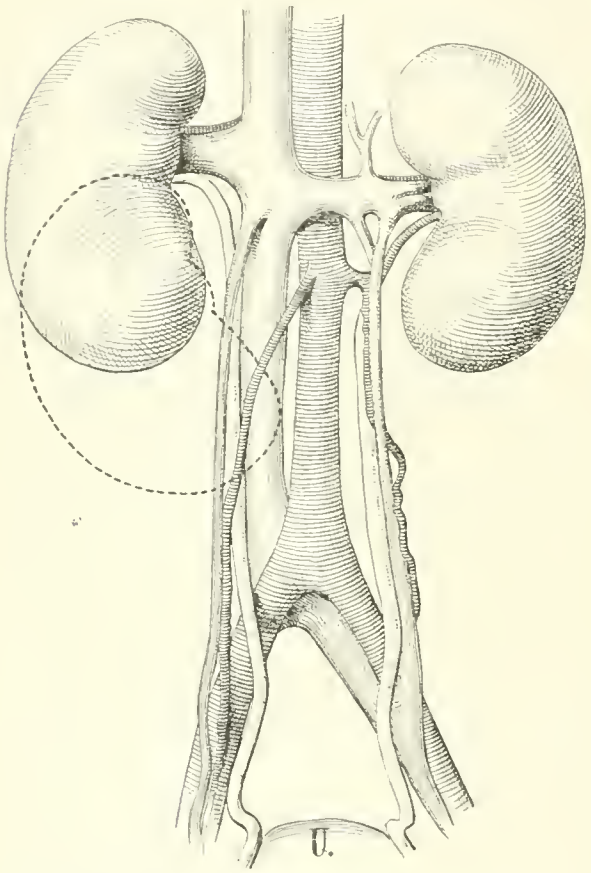
This point is emphasized by the following cases:

A patient who consulted me had been examined by another gynecologist most carefully under anæsthesia, and he discovered nothing but a chronic colitis. He advised horseback exercise, telling her to select the hardest riding horse she could find. She protested that she could not even walk or step down suddenly without experiencing discomfort, and was sure such exercise would add to her discomfort and aggravate her condition. She did not think she could ride even an easy horse. There was not the slightest difficulty in making out prolapse of the right kidney in the erect position, and it was well down below the ribs. She presented typical symptoms of prolapse of the kidney, and pain in the right ovarian region led to suspicion of pelvic trouble, for which she was examined under anæsthesia.

Another patient, who consulted me three years ago, when a diagnosis of prolapse of both kidneys

*Read at the annual meeting of the New York State Medical Association at New York, October 18 to 21, 1904.

was made and operation urged, because there was evidence of commencing nephritis, refused operation, and passed from under my observation. Three months ago she returned and begged me to operate on the kidneys, admitting she had made a mistake in not acting on my advice before. After leaving me she had been examined by another surgeon, who told her one of her ovaries should be removed, and that was the whole trouble. When told of the prolapsed kidneys I had found, he admitted the possibility of the condition, but did not consider it worthy of attention. One operation seemed less formidable to her than two, so she consented, and had the ovary removed, but had not experienced the relief promised, and she was in many ways worse than ever;



for after waiting two years for some good result to be manifested, she broke down completely, and was unfit for her ordinary duties. I fixed her kidneys, and she has made an excellent recovery, feeling already better than she has done in years.

Another patient, who, besides the usual symptoms, had at every menstrual period profuse hemorrhage or an excessive menstruation which exhausted her, consented to operation eighteen months before, when I first made the diagnosis of prolapse of both kidneys. But, unfortunately, she had a brother and brother-in-law, both physicians, who opposed the operation, as well as her husband and mother. She submitted to curettage, which afforded only temporary relief, menstruation becoming excessive again within a few months. She was then sent to a prominent neurologist in this city because of her nervous symptoms. He could not find either kidney prolapsed, and said if they were it was of no consequence. He advised a trip to Europe. She protested that she could not bear the motion of the ship, and did not see how that could benefit her.

I saw the patient with this neurologist, and succeeded in convincing him that both kidneys were prolapsed. I then told him I would prove that all her symptoms were due to the kidneys, and would cure her, for she had taken the matter into her own hands and decided to have the operation, despite opposition. The operation was done only three months ago, and the patient is a perfectly well woman to-day, no longer a sufferer from nervous symptoms; her menstruation is normal, and she is rapidly regaining her lost weight.

Another patient, who consulted me recently and who has submitted to the operation for fixation of both kidneys with gratifying result, complained several years ago of the same symptoms for which she now sought relief. She had undergone curettage of the uterus and repair of a lacerated cervix at that time, upon promise of relief, with disappointment, and had been urged to have the right ovary removed, with which I could find nothing wrong except some slight enlargement, due to congestion.

Another patient who consulted me had worn a belt for three years, and suffered continually until she discovered she could be cured by having the kidneys fixed. The operation gave complete relief of all the pelvic symptoms of which she complained.

I might enumerate dozens of other cases similar to the above, where the patients have suffered for years because the kidneys were either overlooked or their importance disregarded.

In view of the importance of the kidney as an excretory organ, and with the knowledge that its function is seriously impaired by its prolapsed position, it is really a matter of surprise that it is so often disregarded or made light of. I had one patient tell me that her former physician, a very prominent practitioner and consultant, told her that prolapse of both her kidneys, which he made out, was of no consequence; that they would go back into place eventually and cease to trouble her; that an operation should not be thought of. She continued to suffer, however, and was, and had been for years, a chronic invalid in consequence. She was finally restored to health when she consented to an operation.

How otherwise sensible men can disregard this condition and express themselves thus is truly astonishing to the surgeon who is constantly observing results quite the contrary, and who has the opportunity to see the good results from these operations.

It is quite true that many of these patients exist for years with their kidneys out of place, but they are more or less chronic invalids, and their kidneys are diseased. We should ever bear in mind that the prolapse leads to disease of the organ, owing to the continual interference with its circulation and function, and that from constant congestion a chronic inflammation results that may remain in a quiescent or mild state for a while, but eventually atrophy of the organ, or hydro-nephrosis or pyonephrosis may result. It is fortunate that the kidney becomes replaced by the recumbent position, and that during this time it may functionate normally and its circulation be restored, but during the greater part of every twenty-four hours, when the patient is up and about, the kidney must suffer. Besides this, in consequence of its low position in the abdomen, it is constantly subjected to irritation and injury from compression and dragging of the distended colon to which it is attached.

We should not forget also that flexure of the ureter permits accumulation of urine in the pelvis and consequent distention, with pressure upon the secreting structure of the organ and arrest of function.

During the last three years I have had the urine of all these patients coming to me with prolapse of

the kidney examined systematically with the microscope, and find that the majority (75 per cent.) show evidence of already existing inflammation of either the pelvis or urinary tubules. In a paper[1] presented to the New York State Medical Association, October 20-23, 1902, I urged this as a strong indication for operation.

If others could see these kidneys, as the surgeon does, exposed on the operating table, there would be less hesitancy in advising operation for correction of the displacement when it is discovered, and the operation would be more uniformly successful in affording relief. The operation would not be then, as is so often the case now, postponed until structural disease of the kidney has occurred, which may perhaps be incurable.

I find the patient is often given an erroneous idea of the gravity of this operation, as she has been told it is not altogether free from danger. If I can do 197 consecutive nephropexies, in 47 of these fixing both kidneys at the same time, without mortality, any other painstaking surgeon should do as well. Hence it cannot be said that this operation has any mortality.

2030 Broadway.

THE PATHOGENESIS AND TREATMENT OF ŒDEMA.

By WILLIAM J. DOUGHERTY, M.D.

YONKERS, N. Y.

INSTRUCTOR IN NERVOUS DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The pathogenesis of œdema, especially of œdema occurring with Bright's disease in which at times the renal lesions seem quite insignificant, defied for a long time attempts at interpretation. It was not difficult to reconcile the occurrence of œdema or even general anasarca with extensive degeneration of the kidneys, but that slight general lesions, such as those often met with in profoundly œdematous individuals, should be the only cause of such œdema, many, in fact most, observers doubted. However, despite the necessity for a more satisfactory explanation, none of any particular value was suggested until 1898, when Reichel,[1] considering the fundamental rôle played by sodium chloride in maintaining osmotic equilibrium was led to perform some interesting experiments which paved the way to a clearer interpretation of this condition. This observer injected saline solutions subcutaneously into patients suffering from Bright's disease and found that the liquid was slowly absorbed, "producing a sort of local œdema." Following these experiments Hallius and Carrion[2] injected rather strong saline solutions into the blood of animals, and œdema resulted, especially of the lungs. In 1900 Widal and Lisné[3] demonstrated that the freezing point of blood was considerably lowered in chronic nephritis, and as a sequence to this Archard[4] suggested that the œdema of Bright's disease probably resulted from the excessive accumulation of some substance in the blood. As an early contribution to this subject A. Chaufford,[5] in 1900, repeatedly injected a saline solution into a patient with jaundice and scant secretion of urine; the amount of urine was not increased, but, on the other hand, an œdema of the face resulted, "due, no doubt, to the retention of the sodium chloride in the system."

Strange as it may seem, the important facts adduced by these observers were not made use of in a practical sense until last year. On June 12, 1903, Widal and Lensierre[6] read a paper, entitled "Pathogénie de Certains Oedèmes Brightiques; Action du chlorure de sodium ingéré," before the Société Médicale des Hôpitaux de Paris, which served the double purpose of materially adding to our knowledge of the pathogenesis and treatment of œdema and interesting and stimulating the entire profession in France. One result is that since the reading of this paper some fifteen communications on the subject have appeared, all substantiating, and many adding to, what these investigators had said. Widal and Lensierre have contended that in the treatment of œdema we should withhold from the patients so afflicted sodium chloride, because the ingestion of any considerable quantity of this salt by patients suffering from nephritis is often, though not always, followed by œdema. They cited four cases of chronic interstitial nephritis, in which sodium chloride was administered with the intent to induce œdema, but without the desired result. On the other hand, they reported three cases of parenchymatous nephritis similarly treated, two of which developed a pronounced œdema. From these results they are led to believe that in order to produce œdema experimentally in nephritis one must administer the sodium chloride at a time when there exists in the blood a considerable quantity of this salt; and further they believe that the results of their experiments indicate clearly that the quantity of sodium chloride in the blood of persons with nephritis varies from time to time, often very considerably.

Claude and Manté[7] have suggested the administration of sodium chloride in ten-gramme doses as a means of determining the prognosis in chronic nephritis; they have found that the prognosis is unfavorable if, after administering this salt, the amount eliminated in the urine is small, but again Claude and Barthe[8] found that there was an abundance of chlorides eliminated in the urine of patients suffering from chronic nephritis.

Pierre Merklen cites the case of a woman with chronic nephritis complicated with œdema and ascites, who was given a diet of bread, potatoes, and soup, in which great care had been exercised in extracting so far as possible the salt. On this diet the œdema quickly disappeared, but the ascites remained; and he concludes that possibly ascites and œdema have a different pathogenesis. The same patient was later given a milk diet and shortly after the œdema reappeared.

The favorable results obtained by Widal and his associate in the treatment of nephritic œdema by excluding sodium chloride from the diet, naturally led others to resort to the same measure in the treatment of œdema of whatever origin. Pierre Merklen[9] was the first to suggest that sodium chloride played a similar rôle in the etiology of œdema associated with cardiac disease and cited the benefit to be derived in the treatment of such cases by excluding salt from the diet; and Olmer and Audibert,[10] of Marseilles, demonstrated the important part played by sodium chloride in ascites of hepatic origin, and in a subsequent communication they gave further proof of this fact. In connection with this subject the following two cases are of more than passing interest, because the method of applying the remedial measure

[1] "A Study of the Indications for Nephropexy," Medical Record, December 20, 1902.

was so simple that it might be adopted under the most unfavorable conditions. The observations were made at the Bicêtre Hospital in the service of Prof. Pierre Marie, who has very kindly permitted me to quote them.

Case I.—Male, 55 years old, single, employed up to the time of his present illness as fireman in the French Navy. He denies syphilis but admits having had gonorrhœa at the age of twenty-two. His family history is of no interest, his parents lived to old age and his only near relative, a brother, is still living and well. For two years he has suffered from tabes, and now presents the clinical signs of that disease. Three months prior to his admission to Bicêtre Hospital, on February 12, 1904, he had noticed moderate swelling of his legs, but not enough to cause him any appreciable inconvenience until ten days before his admission when it became very much aggravated. On his arrival at the hospital he was found to be in an extremely critical condition; his legs and scrotum were distended to enormous proportions. There was also considerable fluid in the abdominal cavity. His heart presented every evidence of advanced myocarditis and a most striking feature was its pronounced arrhythmia. There was but scant secretion of urine. After five days in bed on a restricted diet of milk and broth and the administration of drugs for the purpose of inducing diuresis, his condition became worse. There was almost complete suppression of urine (100 c.c. in 24 hours), and dyspnœa became a very distressing feature. It was now decided to withhold the salt he had been receiving in broth and articles of diet. Within twenty-four hours the effect of the change was manifest in an increase in the amount of urine. It was now one litre in 24 hours. He continued to improve, and at the end of one week was passing approximately four litres of urine daily. The dyspnœa had disappeared and his legs to the casual observer would suggest nothing abnormal, although at the ankles there was still slight pitting on pressure. The ascites had seemingly disappeared, and there was little fluid in the scrotum. Frequent examinations of his urine failed to reveal the presence of albumin or casts. As might be expected, the heart's action became much stronger, but the arrhythmia being an expression of advanced myocarditis still persisted.

Case II.—Male, 67 years old, single. No occupation. There was nothing in his family history aside from the fact that his mother died of brain tumor. He denies venereal and alcoholic history. In infancy he suffered fom poliomyelitis with resulting deformity of the left leg.

He was admitted to Bicêtre Hospital February 17, 1904, and examination revealed the following: Extensive œdema of legs and scrotum, extreme degree of ascites, heart enlarged to the left, second aortic and pulmonic sounds accentuated; especially the latter. Dulness over the lower portion of both lungs posteriorly and respiratory sounds in this region almost inaudible. Dyspnœa very urgent; urine scanty (less than half a litre), and it contained a trace of albumin, but no casts. Pulse rapid, frequently 130, tension high, volume normal. He, like the other patient, was placed on a diet of milk and broth, with the addition of bread, and was given diuretics, but without effect,—in fact, while under this treatment his condition became distinctly worse. At the end of six days he was given bread and broth unsalted, and here again the beneficial effect of a non-salted diet was observed within the day. His urine became profuse, the œdema lessened and the ascites at the end of one week had practically disappeared. It is needless to add, a corresponding improvement has been noted in his general condition. He now (April 1) voids from two to two and a half litres of urine daily and there is no trace of albumin, casts, or sugar.

Both patients are now permitted the regular ward diet, but on several occasions with Case I. it was foun dnecessary to resume the non-salted diet, owing to a partial return of the œdema.

As one contemplates the facts connected with these cases one of the most striking features that presents itself is the profuse diuresis which quickly followed the reduction in the amount of sodium chloride ingested by these patients. These cases appear clearly to confirm the contention of Archard and others, that organic changes in the viscera are not *per se* the cause of œdema.

It would seem that the same metabolic disturbances which occasion degenerative changes in the kidneys and other organs were also capable of determining (aside from such changes, but unquestionably assisted materially by their presence) the retention in the organism of sodium chloride in abnormal quantity. Taken these two cases alone, it can be seen that the kidneys were not rendered incapable by structural alterations of performing their normal function—for they are now doing that as well as ever—but what would seem to be the most likely explanation is that the watery elements coursing to the kidneys being overcharged with sodium chloride were less fitted for exosmosis than normally. These cases would seem also to disprove positively the contention of A. Chaufford[5] that possibly ascites and œdema have a different pathogenesis, as here we had the ascites disappear as quickly as the œdema on reducing the percentage of sodium chloride.

Bicêtre (Dépt. de la Seine), Paris

THE HISTORY OF TUBERCULOSIS.

By JOHN B. HUBER, A. M., M. D.,
NEW YORK.

From time to time in the history of mankind some one disease or another has popularly been looked upon as the universal scourge. Thus has the Wandering Jew personified the cholera, which in various eras swept away enormous numbers. Dr. Hecker's book on "Epidemics in the Middle Ages" reveals how like a blighting spectre the Black Death stalked through three continents. Before the beneficient discovery of Jenner smallpox had destroyed vast numbers of lives, so that oftentimes cities and towns were much more than decimated, and villages were swept entirely out of existence; so that every other person met upon the thoroughfare would be a pock-marked survivor. The congener of such diseases as these in the present day is tuberculosis; and it is as certain as any human fact that such has been the case from time immemorial. It is likely to have had an existence at least coeval with man; that our primordial ancestors, indeed, were afflicted by it in remote and nebulous ages. To-day the simian suffers from it probably more than does any other living thing.

The physicians of all times, Hippocrates, twenty-five centuries ago, and after him Galen, Celsus and others, had to contend with the Great White Plague, as we have to to-day. Its ravages have not exhibited so terrible an aspect, nor have they been so gruesomely picturesque; nevertheless this insidious disease has always been far pre-eminent as regards the number of its victims. It has undoubtedly been more destructive than the sword to human life. It does seem odd, for instance, that in a city like New York an epidemic, say of smallpox, which may involve the deaths of a mere handful, will create a prodigious panic, while consumption, which in this city destroys every year ten thousand in the most productive periods of life, receives comparatively so little attention. Only the other day the *Sun* reported that one man died in the Bronx Borough of smallpox. "There were three hundred or more people living in two adjoining tenements, and they were exposed to the contagion for fifteen or twenty days." Our Health Department at once sent its physicians, who found the street, in which the death occurred, crowded with excited men and women, many of whom dared not go home for fear of contracting the disease.

Then followed a scene, the description of which is corroborated by that of many a historical incident. The physicians prepared at once to vaccinate all within the sphere of the contagion. The tenants, mostly women and children, were very uneducated and were of all nationalities, mostly Italian; and there was generally a superstitious horror of the proceedings. Here and there frightened people fought fiercely and had to be roughly handled before they could be vaccinated; many submitted only upon threat of arrest and imprisonment. The neighborhood was greatly excited over the news that one individual had died of smallpox, "and the police had to deal with a kind of panic."

If a case of bubonic plague, or of yellow fever, or asiatic cholera, were to develop in this city there would be newspaper "scare head" extras, and the greatest alarm would be felt; and business and traffic to the city from the surrounding country would certainly be demoralized. Yet, as we have noted, but little attention comparatively is given to consumption, a disease much more deadly than all of these put together, and much more inimical to human happiness. The terrible Black Death lived one year in London; it killed fifty thousand. Consumption kills in Europe every year more than a million; in England and Wales alone more than sixty thousand a year. And of all deaths in the United Kingdom between the ages of twenty-five and thirty-five nearly one half are due to this disease.

And all this is so great a pity, because consumption is a disease so easily preventable; and in most cases curable. And though death-rate statistics are impressive enough, still more so are the connotations of sufferings antecendent to death, of the periods of illness in the cases of the vastly greater number of the phthisical who have recovered, and of the hardships visited upon the families and friends of the afflicted.

Among the early Greek physicians there were those who recognized the infective nature of tuberculosis. For instance, a physician of the time of Aristotle asked: "Why are those taken by phthisis, who are brought in contact with the sufferers, and not taken by such diseases as dropsy, fever and apoplexy, however close the contact with sufferers from this disease may be." Phthisis, continues this physician, is obviously infectious, because it spoils the air and makes it heavy, and thus others become infected. That such views as these were generally prevalent may be gathered from a speech by Isocrates, who based the claim of his client to inherit his father's estate on the fact that he had nursed him whilst suffering from phthisis, although his friends had dissuaded him, saying that most of those who nurse in this disease succumb themselves to it. Galen clearly held that phthisis was an infective process, and that it was a danger to live with those who suffered from it. Aphrodiseus declares that the phthisical patient sends out during the expiration bad air, which, being rebreathed by a healthy person would in turn convey the disease to him.

But Aritæus the Cappadocian (50 B. C.) left a description of the consumptive which cannot be improved upon in the present day. It is here reproduced:

"Voice hoarse, neck slightly bent, tender, not flexible, somewhat extended fingers, slender, but joints thick; of the bones alone the figure remains, for the fleshy parts are wasted; the nails of the fingers crooked; the pulps are shriveled and flat, for, owing to the loss of flesh, they neither retain their tension nor rotundity; and, owing to the same cause, the nails are bent, namely, because it is the compact flesh at their points which is intended as a support to them; and the tension thereof is like that of the solids. Nose sharp, slender; cheeks prominent and red; eyes hollow, brilliant and glittering; swollen, pale or livid is the countenance; the slender parts of the jaws rest on the teeth, as if smiling, otherwise of a cadaverous aspect. So also, in all other respects, slender without flesh; the muscles of the arms imperceptible; not a vestige of the mammæ; the nipples only to be seen; one may not only count the ribs themselves, but easily trace them to their terminations, for even the articulations of the vertebræ are quite visible;

and their connections with the sternum are also manifest; the intercostal spaces are hollow and rhomboidal, agreeably to the configuration of the bone; hypochondriac region lank and retracted; the abdomen and flanks contiguous to the spine; joints clearly developed, prominent, devoid of flesh; so also with the tibia, ischium and humerus; the spine of the vertebræ, formerly hollow, now protrudes, the muscles on either side being wasted; the whole shoulder blades apparent like the wings of birds. If in these cases disorder of the bowels supervenes, they are in a hopeless state. But if a favorable change takes place, symptoms the opposite of those fatal ones occur."

The candid student of history must observe that during the darkness of the Middle Ages in which Europe was submerged, Mahommedan Arabia exhibited a wholesome and scientific enlightenment such as is hardly surpassed in our modern civilization. There was inherent in them a wonderful mental development, in which nearly all the arts and sciences were concerned; and among the brightest jewels in this intellectual crown was Saracenic medicine. We can here refer only to Avicenna, the Arabian (1037),* who, like the best observers of antiquity, had definite ideas regarding the infectivity of consumption; he referred "to many diseases which are taken from man to man like phthisis."

After the Renaissance, dissections were permitted and anatomy and pathology came to be more carefully studied throughout Europe, and in the middle of the seventeenth century tubercles or nodules were found in the lungs and first described. The connection between such tubercles and phthisis was first demonstrated by Silenius the Italian (d. 1672).

In the seventeenth century classic "The Practice of Physic by Lazarüs Riverius," published in London, the following appears: "Moreover, there are external causes (of phthisis), as contagion, which is the chiefest; for this disease is so infectious, that we may observe women to be infected by their husbands, and men by their wives, and all their children to die of the same; not only from the infection of their parents' seed, but from the company of him, that was first affected. And this contagion is more easily communicated to them, that are of kin, wherefore it is not safe for a brother or sister to enter into the chamber, for the miasmata, or vapors infective, which come from the lungs, and infect the whole air of the chamber, and being drawn in by others (especially if they are in any way disposed to the same disease) beget the same disease in their lungs."

Morton in 1689 taught that the tubercle was the pathological evidence of the disease in the lungs. And the idea of the infectivity of consumption was developed by the anatomists, especially the Italians Valsalva and Morgagni. Under the influence of the latter, laws were made concerning the spread of phthisis which reflected the spirit and understanding of the Italian people of that time. In 1754, for instance, the sanitary magistrate of Florence asked for an expert opinion from the Florentine Medical College as to what articles would be most likely to be infected from the presence of a phthisical patient, and what means could be adopted to purify them. Antonio Cocchi therefore advised that phthisical patients who lived in large airy rooms exposed to the rising or midday sun, especially during the winter months, do not require more than that their rooms should be well cleaned and always purified by opening the windows as wide as possible. But phthisical patients were not in any case to be put in stuffy rooms with doors and windows shut, for still air increases the amount of putrefaction and makes it more dangerous to others. The sick should only spit into vessels of glass or dried porcelain, which should be frequently and thoroughly cleansed. All small rooms were to be thoroughly whitewashed, but in large rooms it was sufficient to whitewash up to a little above the height of a man. This advice, which reads almost like a circular of to-day on the subject, was the basis of an edict concerning tuberculosis issued in 1757.

The spread of the popular belief in the infectivity of phthisis may be inferred from the statement of Nocard that in 1750 the property of a woman who had died from consumption, after having occupied the bed of another consumptive, was publicly and officially burned in the market place of Nancy.

The present day tendency with regard to the separation of phthisical patients in hospitals had its forerunner in 1760, when a hospital was erected in Olivuzza for the special accommodation of phthisical patients, who were moved there out of other hospitals in order that they might not spread the infection. The modern sanatorium is based upon much the same idea.

In 1782 an edict was issued at Naples ordering the isolation of consumptives and the disinfection of their furniture, books, etc. Except for its historic atmosphere, this decree is in substance quite like a circular issued by a modern health board. Thus: "The Deputies in this capital and the Governors or Locum Tenens in the Provinces should, immediately after the burial of a phthisical patient, be sure to have his rooms cleansed, the floors, wainscoting and ceiling renewed, the wooden doors and windows scrubbed and cleansed, and fresh plants introduced in order that the corrupt and infectious atmosphere may not be communicated to persons who live near; also that they should make use of any other precautions which physicians use in like cases." Again: "The Governors and Directors of the Hospital are ordered to keep apart the clothes, linen, etc., for the use of persons infected with this disease, that they shall be burnt, even in cases of cure, and that to provide new clothes shall be the business of the administration in cases of poverty."

The following penalties were imposed in this decree:

"Those who oppose the officials making their inventories, isolating or removing the clothes to the crematorium, and the cleansing of the places where the patient died, shall be sentenced to three years at the galleys or prison according to the condition of the person, and shall have three years' imprisonment and 300 ducats fine." Pity these things cannot be done nowadays to a few Christian Scientists, Dowieites and the like, without regard to personal conditions. Again: "Regarding physicians who do not reveal the nature of the illness, they shall undergo

*From the excellent book on Consumption by Dr. Hillier, to whom I am indebted for many of the data contained in this paper.

a fine of 300 ducats for the first offense, and for the second ten years' exile." Again: "Those who buy an infected robe shall have three years at the galleys, and those who sell three times the value of the robe sold, as a fine." "Those relations who refuse to send the infected person to a hospital, or remove such an one without the knowledge of the Officer of Health shall have three months' imprisonment if of low birth, or 300 ducats if noble."

In Spain and Portugal laws were also enacted providing for the disinfection of the clothes, beds, etc., of consumptives after their deaths. For instance, in 1839 George Sand wrote, in a letter, of Chopin, with whom she was traveling, and who was already consumptive, although he did not die until some ten years after, thus: "Poor Chopin, who had had a cough since we left Paris, became worse; we sent for a doctor—two doctors—three doctors—each more stupid than the other, who started to spread the news in the island that the sick man was consumptive in the last stage. As a result there was great alarm. Phthisis is rare in these climates, and is looked upon as contagious. We were regarded as plague-infested; and, furthermore, as heathens, as we did not go to the mass. The owner of the little house which we had rented turned us out brutally, and wished to bring an action against us to compel us to limewash his house, which he said we had infected. The law of the island plucked us like chickens." At Barcelona, as they were leaving the inn, the landlord demanded to be paid for the bed on which Chopin had slept, on the pretext that it was infected and that the police regulations required that it should be burned. Fortunately, the science of to-day does not countenance such radical measures.

In 1803 Chateaubriand wrote in Rome to a friend of the death of Madame de Beaumont: "I am in a great difficulty; I had hoped to get 2,000 crowns for my carriages, but, by a law of the time of the Goths, phthisis is declared in Rome a contagious disease, and as Madame de Beaumont drove two or three times in my carriages, nobody is willing to buy them."

Tuberculosis has exerted no little influence upon art; and consumptive models have furnished the inspiration of not a few great paintings. Limonetta Catanea, who sat for Botticelli, died of consumption at an early age. In his "Venus" the artist has faithfully if not intentionally reproduced the sunken cheek, the long, slender neck, the steep, sloping shoulders and the somewhat shrunken appearance of the upper part of the chest. And the model most frequently engaged by Rossetti was also a consumptive. Dr. Hillier well observes that "many of Rossetti's more famous paintings have that expression of suffering which is undoubtedly phthisical in origin. A certain sweet sadness which attaches to these pictures is due to phthisis in the models. It is the appealing sadness of disease, and not the splendid natural beauty of health, as symbolized in the Venus de Milo."

In this connection also Balestier's picture representing Chopin's death has a melancholy interest; as will this very incomplete death roll of a few of the world's great ones who have succumbed untimely to the tubercle bacillus: Maria Constantinova Bashkirtseff, Zavier Bichat, Henry Cuyler Bunner, Frederick Chopin, Stephen Crane, John Godman, John Paul Jones, John Keats, Rene Theophile Hyacinth Laennac, Sidney Lanier, Jules Bastien Le Page, Ethelbert Nevin, Henry Purcell, Elizabeth Felix Rachel, Friederick Schiller, John Sterling, Laurence Sterne, Robert Louis Stevenson, Henry Timrod, Carl Maria von Weber, Artemus Ward, Henry Kirk White, Baruch Spinoza. The Physician Laennac, who himself died of consumption in 1826, was an exhaustive student of the disease; he declared that phthisis followed upon the formation of tubercles in the lungs. Up to the time of Klencke in 1843 the views which were held concerning the infectious nature of tuberculosis were not based upon direct experiment. He injected tubercular matter into the jugular vein of a rabbit, and six months later found tuberculosis in its liver and lungs. And in 1865 Villemin also demonstrated that tuberculosis was a specific disease caused by a specific agent. By injecting tuberculous material from a phythisical patient beneath the skin behind the ears of a previously healthy rabbit, he obtained as a result the development of tuberculous nodes in this animal; while, on the other hand, if he inoculated non-tuberculous material, no signs of tubercles were produced.

But it was reserved for Robert Koch in Berlin, in 1881, to discover the bacillus which he demonstrated to be beyond peradventure the specific cause of tuberculosis. His elaborate series of experiments to this end were conducted in conformity with the following well-known laws, which he himself set down:

1.—The microorganisms must be found invariably in a given disease and in no other, their numbers and distribution conforming to the lesions of the disease.

2.—The microorganisms obtained from lesions of the disease must be capable of reproduction in pure cultures.

3.—These cultivated germs must be capable of producing the disease if inoculated on a susceptible animal.

4.—These artificial lesions contain the specific organisms.

MY EXPERIENCE WITH LIGHT THERAPY.

By JULIUS ROSENBERG, M. D.,
NEW YORK.

In the *New York Medical Journal* of April 24, 1904, I published a preliminary report of cases treated with the ultra-violet light rays. The main symptom of these cases was pain of nerve organ. Even my then limited experience justified the statement "that in light we possess a remedy of no mean order, and one which in the near future will occupy a most exalted position as a therapeutic agent."

Since then I have treated a large number of cases and various forms of disease with, in most cases, very satisfactory results, and I can truthfully state that the blue, violet and ultra-violet rays are almost a specific against pain.

In this, my second, report I publish an additional number of cases, which show that photo therapy has a wide field of usefulness.

Case I.—Mrs. L. J., aged 32 years, a neurasthenic woman, who for years has made the rounds from one physician to another. An extensive laceration of the cervix excepted, a careful physical examina-

tion shows nothing abnormal. The main source of complaint are pains in back of neck extending upward over the head and down the spine. Neither rigidity nor localized tenderness on pressure. Application of light to neck and spine keeps the woman comfortable and away from drugs. No doubt the suggestive influence should, in this case, not be underrated, but even so, is it not well to possess a remedy suitable for these troublesome cases?

Case II.—Mr. R., aged 35 years, a pronounced neurasthenic, contracted gonorrhœa five years ago. This in time involved the posterior urethra, prostatic gland and seminal vesicles, and he now suffers from a chronic catarrhal inflammation of these structures. He complains of disturbed sexual functions, premature emission and a hypersensitiveness in the posterior urethra and over the seminal vesicles. The man has had the best of care, but yet his condition grew steadily worse, and when he came to me was a perfect picture of a mental and physical wreck. The ultra-violet light rays produced considerable relief and improvement. He has gained in weight, and when seen last he was about to start on an extensive business trip. Upon his return the light treatment will be resumed, and I do not doubt but that ultimately the man will be permanently cured.

Case III.—L. B., male, 39 years old, contracted gonorrhœa four years ago. Pain in urethra and perineum; disturbed sexual functions, premature and nocturnal emissions; scanty urethral discharge always present, but most marked in the morning, containing leucocytes and a few gonococcin. Man has been treated with irrigation and local applications, but apparently the disease could not be eradicated. I discontinued all local and internal medication and applied the light over the penis and perineum for one hour daily. The gonococci disappeared from the discharge after six treatments, and now, after two months' treatment, there is no longer any urethral discharge. Patient is entirely free from pain, and his general and sexual condition are markedly improved.

Case IV.—Mr. R., aged 48 years. Specific history—Loss of patellar reflexes, disturbance of bladder and rectum control; slight ataxia of arms; eye symptoms. Romberg's symptoms and ataxic gait absent. Patient complains of sharp tightening pains, for the relief of which he consulted me. Has taken sodium iodide and morphine. The former was continued in increased doses; the latter discontinued. The various coal tar products, although extensively tried, have never, according to patient's statement, afforded relief. After the light had been used for two weeks (ten applications to the spine) a decided improvement was noticeable. The pains had disappeared, and the man's physical and mental condition was infinitely better. He has absolute hope and is firm in the belief that he will be restored to perfect health. Granted that the ultra-violet light cannot cure locomotor ataxia (which belief I share, although some writers claim cures; see *Russ. Med. Zeitsch*, 1903, page 1), these rays can and do afford relief from pain, probably caused by a meningitis, and thus their application is rational and advisable.

Case V.—Mrs. R., aged 32 years, has been suffering for thirteen months from an acute pain extending from the sacrum to the right thigh and leg; walking and sitting postures difficult and painful. Has, as she states, tried everything, without obtaining relief; pelvic organs normal. Applied light three times without much improvement, when patient discontinued the treatment. This woman belongs to that (not small) class of cases who constantly change physicians and treatment without affording either a fair trial. I now refuse to treat such chronic cases unless the patient will agree to take treatments sufficient in number to prove or disprove the value of light therapy in their particular case.

Case VI.—Mrs. L. C., aged 28 years. Last confinement two years ago; labor and puerperium perfectly normal. Since then she has suffered from leucorrhœa and irregular and profuse menstruation. Curetted one year ago without benefit. Examination shows a slightly enlarged, sensitive uterus in normal position. Left tube and ovary enlarged and and painful. Ord. cupri aluminati ℥j to one quart of water, to be used as a daily douche, and applications of light to abdomen. Rapid improvement from the outset. Decrease of discharge and lessened pain. After six treatments uterus smaller and less sensitive; also ovary and tube. The woman was under my care for six weeks, when she was discharged, cured.

Case VII.—Mrs. A. W., aged 32 years; neurotic woman, who gives a history of gonorrhœa and pelvic peritonitis. Had both ovaries removed five years ago. Complains of pelvic pain, varying in severity, but always present; uterus barely movable and sensitive; pressure over the region where the ovaries ought to be causes the woman to cry out with pain. Applied light over the abdomen, and the patient experienced almost immediate relief. After fifteen treatments the woman derived undeniable benefit from the light. The tenderness and pain are no longer complained of, and firm pressure over the parametrium is borne without discomfort.

Case VIII.—Miss R., aged 24 years. Profuse menstruation every three weeks, lasting one week. Passes clots, dysmenorrhœa, backache; colpitis, sensitive uterus. Both ovaries enlarged and painful. Advised curettage, which was declined. Ordered ℞ cupri aluminati ℥j to be dissolved in one quart of water to be used as a douche; Sitz baths; ovoferrin, dessert spoonful after meals. Application of violet rays to back and abdomen. Backache improves. Next menstruation on time, normal in character and almost without pain. Second menstruation also normal. Vaginitis no longer observable; uterus and ovaries normal and not sensitive. Discharged cured. I have treated several similar cases with the most happy results, and I consider the blue and violet light rays a specific remedy in catarrhal inflammations of the female genitals.

Case IX.—Miss R., aged 32 years. Lumbago four weeks. Massage and anti-rheumatic medication caused none or little improvement. Relief followed the first application of the light. Cured after three treatments.

Case X.—Mrs. P. L., woman 48 years of age. Has sciatica in right thigh and legs for three weeks. Pain is constant, extending from buttock to knee and foot. One hour's exposure removed for the time being all pain and discomfort. Ten treatments restored the woman to perfect health.

Case XI.—F. M., aged 36 years. Male, with a syphilitic history; has sciatica for five months. Usual treatment of no benefit. Was treated with *x*-rays, high tension currents, Roman baths, etc., but his condition grew steadily worse. When first seen by me he was in a demoralized mental and physical state. He could neither sit, walk or rest without pain and discomfort After the second application of the light rays improvement began and continued. When he had thirty-three treatments I advised him to leave the hot city and take the baths at Sharon Springs. At that time he could walk, sit and rest without pain and was on the road to complete recovery. This improvement continued uninterrupted, and he is restored to perfect health.

It should be recalled that this man had been under most efficient medical care for about five months, had used every treatment known, yet steadily grew more helpless until the light rays were employed, when improvement and recovery began. Witnessing such results, one ceases to be a skeptic and knows that the chemical light rays are a valuable therapeutic agent if properly used in suitable cases.

Case XII.—Mrs. P., 52 years old; sciatica for two weeks. Pain extends from right buttock to thigh and knee. General condition good; urine normal. Applied light for one hour and asked patient to return the following day for another treatment. She did not show up, but a few days later sent word that the pain has disappeared after the first treatment and she had no need of further light applications.

This case is but an illustration of many similar cases. In acute neuralgias and muscular pain, especially when seen in inception, relief is almost instantaneous, and the best and quickest results are obtained.

Case XIII.—Mrs. H., woman 58 years of age, with a good history. Has sciatica of left leg since three weeks, causing much pain. Walking and sitting posture difficult and painful. Had medicinal treatment, electricity and counter irritation without benefit, but grew more helpless from day to day. The first exposure to the light afforded relief and arrested the progress of the disease. Six treatments sufficed to remove every vestige of pain and restore the woman to perfect health.

Case XIV.—Mrs. R., aged 55 years. General health good; no history of neuralgia or rheumatism; urine negative; pains in right side, extending from buttock to knee, following the course of the sciatic nerve; walking painful. The pain disappeared after two applications of the light (sixty minutes each) and did not return.

Case XV.—Miss L., a nervous woman, 32 years old. Pelvic organs normal; pains starting at right sacrosciatic notch and extending down the leg. The woman states that this pain has existed for three years, and probably was caused by a fall from a bicycle. The pain is at times slight, sometimes unbearable, but always present. When she came to me she was in agony, her walk awkward and painful. Three applications of the light produced a decided improvement. Pain lessened, and the woman is able to flex and extend the leg without discomfort. After nineteen treatments, extending over a period of three weeks, she is entirely free from pain, and the course of the nerve is no longer sensitive to pressure. (This report is written two months after treatment was discontinued, and thus far there has been no recurrence.)

Case XVI.—Mrs. D., aged 65 years; nervous and gouty woman. Lacerations of perineum, descensus uteri, vaginæ et vesicæ. Enteroptosis. Complains of pain between the shoulders, extending down the spine, and aggravated through walking. I have treated this woman for years with salicylates, coal-tar products, massage, etc., without producing any effect or improvement. Her general condition not warranting an operation, the displacement was treated by a ring pessary and abdominal bandage. Although I myself did not have much faith in the efficiency of the light in her case, seven applications of the ultra-violet rays removed every vestige of pain, and for the first time in years the woman can walk with comfort and without pain.

Case XVII.—Mrs. W., aged 48 years; very corpulent. Rheumatoid arthritis of both knees. Has been ill for years; walking difficult and painful. Had five treatments without improvement; treatment discontinued. I think the failure in this case is partly due to the impatience of the woman, who expected impossibilities, and partly to fault of the apparatus. I have under construction an apparatus which enables me to throw concentrated rays over the whole body simultaneously and thus treat the joint from all sides at the same time. I believe a bath in ultra-violet light rays invaluable, not only in diseases of the joints, but also in faulty metabolism, chronic inflammatory conditions of the skin and superficial veins and gouty or rheumatic affections.

Case XVIII.—H. L., aged 42 years, contracted what he terms a heavy cold while duck hunting on a cold and windy March day. Has been in bad health for five weeks. Medication caused no improvement, and the constant desire to cough, the symptom most complained of, remained unchecked. Physical examination showed that the man was suffering from an extensive acute bronchitis, and as drugs had proved ineffective I decided to apply the light rays to his chest. The light arrested at once the copious secretion of mucous, and consequently the cough, and after seven applications the man looked, felt, and was entirely well.

Case XIX.—Mr. A. D., aged 30 years; bronchitis of two weeks' duration. Coarse and subcrepitant râles are heard all over, and his breathing is short and difficult; cough and purulent expectoration, sense of fullness over the sternum, a feeling of lassitude and weakness are the symptoms complained of. Rectal temperature (4 P. M.) 100°. Has had inhalation, guaiacol carbonate, quinine, and heroin without much benefit. One exposure to the light rays for fifty minutes relieved the man of his discomfort in the chest and cough. On his next visit, the day following, he reported decided improvement, and after one week's treatment he was well, and on my advice left the city for a few weeks' change of air.

Case XX.—R. S., aged 13 years, had an attack of influenza (pneumonia?) seven weeks ago. His mother states that his temperature for days had been around 104°, and, judging from his present appearance, the boy must have been quite ill. Cough, and expectoration (no tubercle bacillus), coarse râles

over the large bronchi, crepitant râles and friction sounds below the left scapula. Perspires at night. Rectal temperature (2 P. M.) 100.6°. Has had bitter tonics and cod liver oil. Stopped this medication and ordered massage and violet light rays. Whatever the cause, there certainly was no doubt as to the immediate improvement in the child's condition. The physical signs became less marked, and disappeared; also the cough, expectoration, and sweating. The temperature was normal after the fourth treatment, and within three weeks the boy had regained his normal weight and health.

CASE XXI.—S. B., woman, 54 years old. Well nourished and healthy appearance. Consulted me for an obstinate cough and dyspnœa. She states that she has been in bad health for years. Pulse rate normal, of high tension; heart normal; except a few bronchial râles, examination of chest negative; intestines distended; liver projects two fingers below free border of ribs; varicose veins; œdema of both ankles; urine contains a trace of albumin; chronic constipation. Ord. general massage, pill of aloes, belladonna, and podophyllin at bedtime; syr. ferri iod. after meals, ultra-violet light to chest. The woman was much benefited by this treatment, and her cough and asthma, to her the most serious symptoms, were favorably influenced through the applications of light.

CASE XXII.—Mrs. D. R., sixty years of age. Chronic pulmonary emphysema, with cough and dyspnœa. Has had much medication, but only obtains relief from a pill containing codeine, camphor, and ipecac. The patient derived much benefit from the light and is able to get along without opiates.

CASE XXIII.—Mrs. N. K., aged 24 years. Was brought to my office in a carriage, and states that a physician who had just seen her had diagnosed her case as angina pectoris. Suffers from agonizing pain over præcordium, which extends backward to the left scapula. Heart action accelerated, but regular; no murmur or friction sounds. Diagnosis, intercostal neuralgia. Application of the light rays caused immediate relief, and after the second treatment the woman was and remained free from pain.

CASE XXIV.—Miss L., aged 26 years, nervous and anæmic woman. Irregular, scanty menstruation; constipation; acne pustules over face and chest. It is for the acne the woman asks relief, as local and general treatment had been of no benefit. Ordered iron after meals, laxative pill at bedtime, ultra-violet light to face and chest. Four treatments arrested further formation of pustules, and after sixteen treatments no trace of acne was to be seen.

CASE XXV.—Mr. H., aged 40 years. Acne rosacea has existed for about four months, involving the right cheek and nose. Improvement after second application. Seven treatments sufficed to remove, a few scars excepted, every vestige of disease.

CASE XXVI.—Mr. R., aged 34 years. General health good; urine negative; furunculosis of right forearm (extensor surface) for nearly two months; boils recur in spite of local and general treatment. Applied light for two weeks; no other treatment. Furuncles have disappeared and new ones have not formed again.

CASE XXVII.—Mr. K. L., aged 46 years. Run down condition; urine negative; furunculosis of neck. This has existed without intermission for almost one year. Ord. syr. ferri iod. after meals, application of light to neck. After ten treatments no new abscesses. Continued applications for one month; no other treatment. Patient is entirely well, and, old scars excepted, the neck is normal in appearance.

In all these cases I used a 35-ampere arc with mirror reflectors and iron-carbon electrodes. I consider the length of exposure and the iron electrodes of importance. The iron-carbon arc is very rich in chemical rays, and although other rays are not without value, the ultra-violet rays have probably the greatest potency. The penetrating power of the latter is still subject to discussion, most investigators being inclined to believe that it is slight, hardly beyond the superficial skin layer. From the results obtained in affections of deeper structures I should judge that laboratory experiments are not conclusive. How are we otherwise to explain their curative influence in diseased conditions of the deeply situated nerve trunks?

My present experience with a large number and varieties of cases treated leads me to form the following conclusions:

I.—The ultra-violet light rays obtained from an iron-carbon arc of high amperage are a specific remedy in acute muscular pain, such as lumbago, torticollis, and pleurodynia.

II.—In cases of acute and chronic neuritis these rays will always relieve pain, and in most cases, especially acute forms, effect recovery.

III.—The bactericidal powers of the chemical light rays are easily demonstrated in inflammatory conditions of the skin of parasitic origin. In acne and furunculosis the curative effect is both prompt and certain.

IV.—My results in rheumatic arthritis have not been encouraging, thus differing from those reported by German authors. This may in part be due to the limited number of treatments permitted.

V.—In acute and chronic pleurisy and bronchitis the application of the ultra-violet rays is undoubtedly beneficial. I also believe that these rays could be of assistance in the treatment of pulmonary tuberculosis.

VI.—My results in gonorrhœal peritonitis and catarrhal inflammation of the deep urethra and adjacent structures are certainly encouraging, and justify further trials.

VII.—I believe that the ultra-violet light rays will be of benefit in gonorrhœal and tuberculous infections of the joints; also that the pains accompanying locomotor ataxia may be relieved and controlled.

The report of above cases and those formerly published do not represent my whole experience with ultra-violet treatment, but they are fair representatives of the various types. To report more cases would only lengthen the paper, without adding to its interest.

772 PARK AVENUE.

A New Ray.—M. di Brazza of Liège claims to have discovered a new sort of way which he calls the *i*-rays. The brain is the seat of these as it is of the hypothetical *n*-rays, but the *i*-rays differ from the *n*-rays in that they pass through moist substances.

AINHUM.—REPORT OF CASE.*

By HENRY N. BLUM, M.D.

NEW ORLEANS, LA.

Among the synonyms applied to this affection we find ayun (Yorubas); sukha pakla (Hindu); guijila, or quigila (a condition present in leprosy and confused with ainhum); gafeira (Portuguese); fadiditi (Island of Nossi-Be, near Madagascar). The Nago negroes called the disease ainhum. The Yoruba negroes call it ayun. Bordier says that the word ainhum is the negro Brazilian patois for fissure. Other authorities give the word a different origin, meaning in one case "to saw," or, according to another source, "constriction."

Ainhum is a peculiar disease, which occurs almost exclusively amongst the dark-skinned races of certain tropical and sub-tropical regions, and is characterized by a progressive constricting sclerotic ring around bases of the digits of the hand or foot, especially selecting the little toe of either or both feet, and ending in a gradual amputation of that portion of the affected member distal to constriction.

A review of the literature concerning this disease is interesting and important, showing it to be a comparatively modern condition and slowly changing in its geographical distribution. Formerly the disease was characteristic of the negro race, but it has gradually become a disorder to which other races may be subject. This is probably due to the emigration of the negro from his former home. If the members will bear with me for a little while I will cite some cases from the literature that may prove interesting to some who have not seen the disease, and particularly interesting to those who have met with similar cases in practice.

Beginning with the first recorded case of ainhum reported in a paper read by Clarke before the Epidemiological Association of London, in 1860, of a patient seen on the west coast of Africa (Clemon's "Geography of Disease"), the literature is full of cases from all parts of the world.

Da Silva Lima of Brazil (*Medical Gazette* of Bahia) was the first to recognize this condition in the Western Hemisphere. This was in 1867, and his other contributions in the *Archives of Naval Medicine* in 1867, the *Archives of Dermatology* of the same year, and the *British Medical Journal* of January 3, 1880, show him to have been a hard worker in this direction.

Dr. John Del'Orto, in a paper read before the New Orleans Medical and Surgical Association in October, 1880, referred to a strange disease called ainhum, and directed the attention of the society to a paper read before the Imperial Academy of Medicine in Brazil in 1876, by Dr. Jose Periora Guimaraes. Dr. Del'Orto gave Moncorvo credit for reporting the first case, but this was evidently a mistake, since Clarke's paper was read 16 years previous to this time. The paper of Del'Orto shows that the disease had not been recognized in New Orleans at this time. Duhring reports a case from Virginia in the *American Journal of the Medical Sciences* for January, 1884. This was in a negro of 50 years, and had been present in both little toes, the first symptoms showing at the early age of ten years. Both parents had had the same condition. Microscopical examination by Dr. Henry Wile showed a picture of inflammatory edema, the arteries being thickened and filled with blood corpuscles and the veins absolutely empty. This was about the first thorough microscopical study given ainhum.

Dr. R. H. Day, of Baton Rouge, an ex-President of the Louisiana State Medical Society, reported two cases in the *Medical News* of September 29, 1888. Dr. J. L. Deslattes, of St. James Parish, had seen four cases at that time in his locality. In the *New Orleans Medical and Surgical Journal* of February, 1889, E. D. Martin, then a student in the Charity Hospital, reported the first case of ainhum recognized in New Orleans.

We have a report from Surgeon Todd in the *British Medical Journal* of February 21, 1891, which shows the disease was not uncommon amongst the Krumen of Africa. Cecil Digby, in the same journal of June 28, 1891, refers to a case of Dr. Eyles in which the fourth toe was involved, and to another

in which the second finger was the seat of trouble. Out of twelve cases seen by Digby, two showed the condition in both feet, the left more often affected than the right. He thinks that the custom of wearing toe rings have some relation to ainhum. Eyles' investigation of the pathology shows that the connective-tissue hyperplasia strangles the epithelium by shutting off the blood supply, and finally causes it to undergo horny changes.

The first cases from Egypt were reported in *The Lancet* of July 23, 1893, by Mr. Nelton and Dr. Croswell.

A case interesting in its being reported so far north is that of Dr. F. J. Sheppard, seen in the Montreal General Hospital and reported in the *American Journal of Medical Sciences*, Vol. 93, 1887. This was in a negro of 47 years, a native of North Carolina, but a resident of Canada for 20 years. A unique case was that reported by A. E. Barrett Hine, in *The Lancet* of January 25, 1895. Patient was a Lascar of 22 years, and ainhum was present in the fourth toe of right foot and fifth of left foot.

Dr. Pothier made the first microscopical study of this condition in New Orleans. This was in a case reported by Dr. H. J. Scherck, in the service of Dr. R. Matas, in the *Medical Mirror* of May, 1997. Examination showed a connective tissue hyperplasia.

*Read at a meeting of the Orleans Parish Medical Society, July 9, 1904.

The most thorough work done was in the case of J. B. Herrick and reported in the *Philadelphia Medical Journal* of February 5, 1898. A skiagraph accompanying article shows the condition beautifully. In this case there was no sign of leprosy, nor was there any nervous manifestation. Examination by Hektoen showed no tubercle bacilli or lepra bacilli present in tissue. Spots of vitiligo were present on both feet.

In the *Tulane Phagocyte* of January, 1904, is a report of a case by Lazard of a patient seen in the Charity Hospital in Matas' service, November, 1903, and brought before the surgical class for discussion. The patient was a negro male of 33 years, a native of Ohio, but a resident of New Orleans for six years. Ainhum was present in both little toes. The disease had caused neuralgic pains for several months. Matas and Del 'Orto were the first to recognize the disease in New Orleans (Dennis' System of Surgery). The disease occurs amongst the dark-skinned races of Brazil, the Atlantic States of America, the coast of Western Africa, West Indies, Egypt, the Polynesia, Madagascar, India and China. No case has ever been reported from Europe. Dr. Sheppard's case from Canada is unusual. Matas, in the "Transactions of the American Surgical Association," 1896, quotes Bordier, who refers to Franton's and Mirault's cases, which occurred among Aryan races. Dr. Brun records a case in a Syrian woman of Symrna.

Ainhum is very insidious, the condition progressing slowly for years, in some cases lasting over a term of 20 years. On the other hand, it may have reached its last stage in the short time of three years. On account of the lack of opportunity, proper study has not been given this peculiar anomaly in its early stage. From the information given us by our patients we know that the disease is painless in its beginning, but as the constricting ring grows tighter and fissures appear at the bottom of the constricted portion pain becomes very troublesome. The affected member is usually amputated spontaneously, after complete atrophy occurs at sulcus, the toe usually dropping off while walking.

Ainhum is a local condition, there being no manifestation, except on the toes or fingers, and it never recurs at site of amputation. Its duration is sufficient to differentiate it from Reynaud's disease, even if it were not that the constricting "scleroderma" is the characteristic feature of ainhum. Leprosy is sometimes confused with ainhum, but in leprosy there are changes to be seen in other parts of the body, and the specific bacilli are to be found in the diseased tissues. Similar processes in leprosy cause no pain, because anæsthesia is present. Such is not the case in ainhum.

Although forty years have elapsed since this disease was first brought to the attention of medical men, very little has been done to search out its real cause. This is due in some measure to the fact that the cases are not seen until the process has so far advanced that permanent changes have resulted. Should a case be seen in its incipiency, before atrophic alterations have completely destroyed the tissues, some information might be obtained by a thorough microscopical study. Very rarely has the disease been seen to exist in the Caucasian, though it is sometimes present in countries where the white man reaches his highest type. This is peculiar, in view of the fact that Park deems it undoubtedly an infectious disease. In the "International Textbook of Surgery" Matas asserts that it is a tropho-neurosis, and this, to my mind, is much nearer the truth. He cites Mason on the other hand, who believes it keloidal. I have seen a keloid in the white man. Von Winckler's cases of ainhum, in which not one of his twenty patients had worn toe rings, is an argument against local infection. Guyot's case seen in utero is very probably a case of mistaken diagnosis, since in this patient the disease extended up the leg. From the information obtained by the successive histological studies, it is quite rational to believe that we have to deal here merely with trophic changes excited by trauma at seat of trouble. It is a peculiar fact that ainhum is seen usually amongst those whose feet are exposed to traumatism while walking, but, on the other hand, this would not explain the cases seen on the digits of the hand.

A. La Dantec says there are two characteristic pathological stages, sclerogenic and fatty. The tissues on further end of toe become altered in shape until a globular form is assumed. This is due to the lipoma-like process. Manson in his "Tropical Diseases," third edition, 1903, says that the absorption of bone is due to a fatty degeneration, and attributes ainhum to fibrous changes excited by traumatism, the fibrous ring being an exaggerated effort to heal.

Case.—My patient, Rebecca T., a negro woman of 65 years, came to my clinic at Touro Infirmary March 21, 1904. Owing to her being deaf and her intelligence of a very low order, it was impossible to get a satisfactory history. With the assistance of her daughter, whose lips the patient could read, I was enabled to learn that the disease had been present at least three years, for during that time she had suffered pain because of the deepening isthmus. Ainhum was present in little toe of right foot. Around the plantar fold of this toe was a very tight sclerotic ring. Spots of pigment atrophy were present on both legs, but I could learn nothing from the patient concerning this condition.

On March 23 the toe was disarticulated at the metatarso-phalangeal joint. Cocaine anæsthesia was employed. A skiagraph taken at the time shows the condition very clearly, the ends of the divided bone being seen quite distinctly. During the operation the strangled portion of the toe dropped off, and was saved for future study. Unfortunately, the proximal part was lost. I say unfortunately, because much more information could have been obtained from the pathological changes in this portion of the toe.

In due time the wound healed without any further manifestation. I saw the patient last week, and the cicatrix was in a healthy condition. The patient at this time had œdema of lower extremities, the result of an old endocarditis.

In this case the patient was living amidst civilized surroundings, and it is very probable that she wore shoes as much as is common with those of the same social status. She wore no toe rings. Whether or not the white spots to be seen on the lower legs had any connection with the trophic changes present in the toe is a matter that might be discussed with in-

terest, and I would like to have an expression on this subject from those familiar with diseases of the skin.

In conclusion I wish to state that this is the first report from New Orleans in which the patient is a female, all the other recorded cases having been seen in the male.

NOTE.—July 12. Since reading the above paper (July 9) I have found that the first case of ainhum seen in Louisiana was in a patient of Dr. A. C. Love, in 1882, in the town of Donaldsonville, and reported by Dr. Joseph Jones in his "Medical and Surgical Memoirs," Vol. II.

124 BARONNE STREET.

REPORT OF TWO FATAL CASES.*

1. HYPERTROPHIC CIRRHOSIS OF THE LIVER; TALMA'S OPERATION. 2. CANCER OF THE HEAD OF THE PANCREAS; CHOLECYSTENTEROSTOMY.

BY IRVING S. HAYNES, PH.B., M.D.,
NEW YORK.

PROFESSOR OF PRACTICAL ANATOMY, CORNELL UNIVERSITY MEDICAL COLLEGE, VISITING SURGEON TO THE HARLEM HOSPITAL, ETC.

IT is not often that we deliberately report our fatal cases—the successful ones are far more pleasant to rehearse—but I think the following cases, under my care this winter, are worthy of consideration because of the nature of the disease present and the reasons why operative interference failed to benefit.

CASE I. *Hypertrophic Cirrhosis of the Liver.*—John T., age 45, married, Irish, was admitted December 2, 1903. Family history was negative. Says he was never sick before. Has been a heavy whiskey drinker.

He first noticed an enlargement of the abdomen about one week before admission. Has had no pain; the bowels are quite loose, and the night before admission he passed some blood in the stools. Skin is slightly jaundiced; the veins radiating from the umbilicus are becoming prominent. The liver is markedly enlarged and extends about three inches below the costal margin. Abdomen contains a large amount of fluid. There were no other symptoms. Temperature 99.2°, pulse 108, respiration 24. Medical treatment was continued for ten days without benefit. Then the patient consented to an operation, which was performed on December 20, 1903.

Anæsthesia.—An incision four inches long was made parallel with the costal arch. A large amount of ascitic fluid escaped on opening the peritoneum. The liver was a large nutmeg one, extending three inches below the ribs. An interesting condition was found on examining the region, in that nature had attempted to establish measures for the relief of the portal obstruction, for the omentum, thickened and with tortuous and dilated vessels, was found adherent to the parietal peritoneum and lower edge of the liver over an area about two and one-half inches in diameter. The collateral circulation was very well established, but evidently was not sufficient to compensate for the portal interference, inasmuch as there had been no improvement in the patient's condition. It was necessary to strip up these adhesions before further progress could be made. This was followed by considerable venous oozing that yielded to hot compresses. The opposite surfaces of the liver and diaphragm were scarified with a stiff toothbrush, the omentum tucked well in between the two, and the incision in the abdomen closed by layer sutures. The first two days after the operation were uneventful.

On the evening of the third day the temperature went up to 101.8°, pulse 110, respiration 22. There was considerable abdominal pain, relieved by ice bags and morphine. The fourth day the temperature fell, but the pulse increased in frequency. On the evening of the fifth day after the operation the temperature reached 102.6°, pulse 136, and respiration 30. He died during the forenoon of the following day. No autopsy was permitted.

In the Year Book of Medicine and Surgery for 1904 are extracts from several papers on this operation. Greenough reports on 105 cases of liver cirrhosis which presented symptoms of ascites. Forty-two per cent. were improved and 58 per cent. not improved by Talma's operation or one of its modifications. The mortality within thirty days was 29½ per cent.

Arcoleo operated eight times for ascites due to cirrhosis of the liver. Three patients died shortly after the operation. Four patients were neither improved nor injured by the operation. Two of the patients were suffering from marked hypertrophic cirrhosis, and the operation in these resulted in marked temporary improvement.

Mori analyzes thirty-seven cases. Thirteen died, thirteen were cured, ten remained stationary, and one improved. Mongour places the immediate mortality at 35 per cent. and Friesch at 45 per cent.

Harris (*Journal of the American Medical Association*, October 31, 1903), reports six personal cases. 1. Male. 56. Hard drinker, atrophic liver, enlarged spleen, jaundice, ascites:—duration one year. Operation, no improvement. Died in three weeks. 2. Male. 55. Hard drinker, atrophic liver, enlarged spleen, ascites:—duration four months. Operation, no improvement. Died in two months. 3. Male. 40. Free drinker, slight jaundice, ascites, spleen enlarged, liver cirrhotic. Operation, apparent improvement, but died in less than one month. 4. Male. 43. Used tobacco and alcohol in excess. Duration, four years. Ascites, icterus present. Operation. Adhesions so universal nothing was done. Patient died six days after operation. 5. Male. 36. Used tobacco and alcohol to excess. Duration, about one year, but abdomen began to swell only three days previous to entering hospital. Jaundice, ascites. Operation. Omentum fixed behind rectus muscle. Died on second day. 6. Female. 43. Syphilitic. Abdomen began enlarging nine months ago. Ascites. No jaundice. On operation omental and visceral adhesions so extensive nothing further could be done. No improvement from operation. Death followed in some months (not stated).

Lenzman (*Journal of the American Medical Association*, December 26, 1903), advocates the operation of epiplopexy in every case of atrophic cirrhosis of the liver when the organ is not perceptibly shrunken, but the signs of congestion in the portal veins, development of ascites, etc., are noticeable. Also when the liver is somewhat shriveled and there is more or less ascites, but the liver tissue is functionating to a certain extent, as shown by the absence or slight degree of icterus. On the other hand, he thinks there is little prospect of success when the icterus is pronounced, or when there is urobilinuria, or when hemorrhages from the mucosæ, delirium, etc., indicate complete or considerable insufficiency of the liver function responsible for the production of bile. The heart action must still be good to insure the development of collateral circulation.

The operation is a serious one. The immediate mortality being very high, and the ultimate results not promising, except in a very few cases that might have lived a long time, comparatively, under medical treatment alone, we are forced to conclude that the

* Read before the Society of the Alumni of Bellevue Hospital.

operation is still under judgment, and time alone will enable the indications to be more sharply drawn.

Case II., *Cancer of the Head of the Pancreas.*—Patrick Q. Age 43, Irish, married, engineer, entered hospital October 31, 1903. Family history was negative. He was a moderate drinker and heavy smoker; denies any venereal history. He has had malaria, but no other illness is remembered.

He began in March, 1903, to have girdle pains around the abdomen, but never at any time had a distinct colic. Jaundice appeared with the pain and has persisted, varying in degree and of late becoming much worse. Has lost fifty pounds during the past eight months; his strength also has diminished and he tires easily.

The bowels are regular, the movements being clay-colored. The tongue is heavily coated, but appetite and digestion are good. He sleeps well. At times has been troubled by frequent micturition at night.

Urine: sp. gr. 1.024 alkaline; albumin, a trace; sugar negative; bile is present; microscopical examinations negative. Blood: leucocytes 8,200; no malaria plasmodium. Fæces: offensive odor; clay-colored; fluid; fat globules and crystals abundant. Temperature 100°, pulse 84, respiration 24.

Abdomen generally distended and contains fluid. Skin everywhere deeply pigmented from severe and long-standing jaundice. Slight tenderness at Robson's point. Abdomen so much distended that nothing in the shape of a tumor could be felt.

Liver apparently not enlarged—crowded up under costal arch, which was flared out—from abdominal pressure.

On the evidence of a long-continued and persistent jaundice, loss of weight, and cancerous look, and on the absence of biliary colic, the diagnosis was ventured of a malignant growth, probably implicating the head of the pancreas, as there was evidence of arrested pancreatic juice, in that free fat was found in the stools. Previous to operation, the pulse varied from 80 to 100; the temperature was around 101°; respiration 22 to 24. There was a steady loss in flesh and gradually increasing weakness. No change in jaundice. Very little pain at any time.

November 7, 1903, operation. Chloroform and ether in combination. Vertical incision in outer margin of right rectus muscle from costal margin downward for five inches. On opening the peritoneum a large quantity of bile-stained serum escaped. This colored the sponges and towels very markedly. A large gall bladder distended with fluid bile, but no calculi at once came into view. The abdominal distention and ascitic fluid prevented its recognition before the operation. The liver was enlarged and its sharp lower margin changed to a rounded, blunt one. Palpation of the duodenum and pancreatic head showed the presence of a hard nodular mass, not very large, but distinctly palpable. No attempt was made to enucleate it. By a small-sized Murphy button, the fundus of the gall bladder (after draining off the bile), was joined to the opposing transverse colon. The union between the two viscera was apparently so even and firm that no supporting sutures were added. Here is where an error of judgment occurred. The region of the anastomosis was drained by a small gauze wick on either side, with a medium-sized rubber drain placed within the gauze, and the wound closed by layer sutures.

The bowels moved freely on the second day, and the fæces were bile-stained.

On the third day the rubber drain was removed. There had been considerable escape of ascitic fluid. Diarrhœa (eight stools) appeared. On the fourth day the bowels operated seven times. On the fifth day the diarrhœa was controlled by bismuth subgallate. Temperature 99°, pulse 82, respiration 24. The condition was greatly improved as regarded the general appearance, and the jaundice was much less.

On the seventh day the gauze drains were easily removed. The wound elsewhere was united by primary union. On the ninth day the wound was dressed by the house surgeon; the drainage tract had healed. The patient complained of some pain in the abdomen, but it was not localized, and there was nothing on palpation.

On the tenth day the case was reported to me. Temperature 102.8°, pulse 120, respiration 36, stools 3. So far as we could make out, there seemed to be no localizing abdominal symptoms. The eleventh, twelfth and thirteenth days were marked by a subnormal temperature—97°, 96°, 96.4°—with gradual decline and death.

Autopsy limited to the seat of operation: Liver contained no evidences of malignant growth. The gall-bladder was also free from cancer. The head of the pancreas was the seat of a hard cancerous growth occluding the common bile and pancreatic ducts. The abdominal cavity was filled with bile-stained fluid. There were no adhesions. The cause of death was the failure of the gall-bladder and colon to unite, only one-half of the area constricted by the Murphy button had joined. The rest had simply been held in apposition by the button, and as soon as the compressed tissues had sloughed and freed the button, the two viscera fell apart. The button was free in the colon and near the attempted cholecystenterostomy. No gallstones were present in the biliary system.

Here, then, is a typical case of cancer of the head of the pancreas, in which a diagnosis of the condition was made before, and confirmed by, operation and autopsy; in which a palliative operation was undertaken for the relief of the jaundice by performing a cholecystenterostomy, and an error in judgment was made by trusting entirely to the mechanical means for holding the gall-bladder and intestine in apposition. The failure of this approximation to produce firm union allowed leakage of bile after the slough had freed the button.

Park, quoted in the Year Book, 1904, p. 202, says cancer of the pancreas is far more common in the head of the organ. The symptoms he divides into those pertaining to the pancreas itself and its functions, those pertaining to adjoining and related organs, those indicating dissemination of the cancer, and the tumor itself. Early symptoms are vague, and indicate some digestive disturbance. Fatty stools are occasionally noted. Should jaundice follow and glycosura, with pain in the epigastrium, and emaciation, pancreatic cancer is probable. Pain is a very uncertain feature, though it may appear early. Ascites may result from pressure on the portal vein. Late in the disease a tumor may be felt, which resembles a growth in the pylorus, but is deeper and more fixed. The disease runs a rapid and fatal course. Cholecystenterostomy is thought to be a better operation for the relief of symptoms than cholecystostomy.

1125 Madison Avenue.

An International Congress on Tuberculosis will be held in Paris October 2-7, 1905. The president of the Pathological section will be Dr. Lannelongue, and of the Social section, Dr. Landouzy.

AURAL REFLEX PHENOMENA.

By J. J. RICHARDSON, M. D.,
WASHINGTON, D. C.

A GREAT variety of symptoms are ascribed to the ear. Many of them on first consideration are perplexing, but a careful research into the minute anatomy and physiology of the organ enables us to account for them on purely anatomical and physiological grounds. It is not my purpose in this short paper to take up at length the subject of aural reflexes, but I simply desire to point out the necessity of a careful examination of the ears as a possible source or seat of disease in certain cases of obstinate and obscure symptoms which are usually referred to other and remote organs. A few examples of these cases which have come under my own personal observation I deem of sufficient interest and importance to bring before the notice of the profession. A great deal has been written on reflexes of nasal, laryngeal, and uterine origin, but the literature of aural reflexes is very meager. We are responsible for this ourselves. It is not that these conditions do not exist, but we fail to associate certain symptoms with the ear when they actually occur. That they are not more frequent is to be wondered at, when we consider its rich nerve supply and complex nervous anastomosis. It is so extensive that a small lesion may cause an impression to be made on several afferent nerves at the same time and set up any number or variety of symptoms. Take the meatus externus for example. The inferior maxillary division of the fifth nerve carries sensory impressions from it, including the dermal layer of the membrana tympani, to the brain. The auricular branch of the pneumogastric ramifies the cartilaginous canal. In addition to these there is a plexus of nerves composed of fibers from the fifth, glossopharyngeal and sympathetic. This very large and varied nervous supply is not the only reason why the ears should be considered as a favorable starting point for reflex disturbance. A reflex phenomenon following an irritation or stimulation of a sensory nerve is more marked the closer the irritation is applied to the nerve center. That is to say, the shorter the distance an impulse travels, the more profound or marked will be the results. As the nerves that supply the ear are cranial, it is apparent that the nerve tissue separating them from the brain is of no great length. From this we should naturally expect nervous disturbances to have their origin frequently in pathological conditions of the hearing apparatus. That many functional and spasmodic diseases have their origin here no one who daily treats aural diseases and carefully observes every symptom before and after treatment will for an instant question.

Among the diseases that have been attributed to the ear and improved or cured by directing the treatment t othis part may be mentioned epilepsy. Cases of this nature have been reported as resulting from irritation in the meatus auditorius externus and as a complication of chronic suppurative otitis media. Instances of morbid irritability, loss of memory, and melancholia are of not uncommon occurrence in chronic catarrhal and suppurative affections of the tympanum. A train of symptoms at times is observed from impacted cerumen, which careful diagnosticians have mistaken for those of incipient locomotor ataxia. In each there may be impairment of hearing, uncertainty of gait, and a feeling as if walking on a padded floor.

Persons afflicted with ear disease frequently *faint*. It occurs entirely too often to warrant us in excluding a relation of cause and effect. The phenomenon is sometimes seen in minor operations upon the ear. It differs from the ordinary syncope in that there is less anticipation, with an absence of pallor, sighing, dilated pupils and nausea. The patient will simply roll up his eyes and slide down in the chair, when unconsciousness supervenes. In the cases which I have had the degree of pain suffered has had little reference to the excitation of this reflex. It depends on the temperament of the individual, rather than the degree of discomfort experienced. Ankylosis of the ossicles and obliteration of the round window are the most prominent middle-ear etiological factors in its production. The fenestræ seem to act as a sort of safety valve, as it were, so that when their function is impaired every movement of the ossicles causes a shock or concussion of the semicircular canals which preside over the equilibrium of our bodies, and giddiness is the result. This is the most excessive form of aural vertigo, and is not to be confounded with Menière's disease. Vertigo frequently occurs in syringing the ear, and especially when the water is cold and we force the current directly against the tympanic membrane instead of along the side of the canal. The pressure against the membrane forces the ossicular chain inward, with the resulting alteration in the intratympanic pressure and irritation of the ampullary nerve filaments. The exciting causes within the external meatus may be a diffused or circumscribed otitis media, polypi, exostoses, or impacted cerumen. The latter is by far the most common one which we meet. It may or not be associated with impaired hearing. The wax may remain a long time without causing any symptoms, and then vertigo or deafness come on suddenly upon some displacement of the mass resulting from a jar, picking the ear, or getting water in it. It does not apparently occur in children as the result of lesions confined to the meatus externus and tympanum, while in adults diseases of these parts are the most prominent exciting causes. In this regard it is like tinnitus aurium. The irritation at times may be so powerful as to affect another center physiologically connected, namely, the vomiting, and in such instances the mistaken diagnosis of gastric vertigo is frequently made. An instance of this kind has recently come under my observation, and the vertigo, vomiting, and deafness disappeared after the removal of a huge mass of hard, tightly impacted cerumen.

Von Trolsch reported an interesting case as showing the similarity of the symptoms and those of traumatic cerebral irritation. It was that of a man who become suddenly deaf and attacked with vertigo after a fall. He was treated for some time for cerebral trouble, when v. Trolsch discovered and removed a large mass of cerumen from the ear, with the result of curing the deafness and causing the vertigo to disappear. The fall had displaced the wax in the meatus and caused pressure on the drum membrane, which up to that time had been unimpaired in the performance of its function.

There undoubtedly exists a relationship between the larynx, its adjacent parts and the auditory ap-

paratus. Frequently, when we have obstinate hacking coughs that have resisted all forms of treatment we may find the seat of the trouble in the ear. Singers sometimes complain of pain in the ears on excessive use of their voice, which shows some sympathy existing between the two parts. The mere introduction of an aural speculum will often set up a cough and tickling in the larynx which continues as long as the instrument remains in the ear. With the object of at least approximating the percentage of the subjects in which these reflex disturbances exist, I have examined carefully the ears of one hundred persons, and by irritating the external meatus artificially I was able to set up coughing paroxysms at will in seven, vertigo in two, and vertigo with nausea in one. Those whose ears were examined were unaware of the object of the examination.

Asthma is another disease which may be of aural reflex origin from irritation of the auricularis magnus nerve, which communicates at times with branches from the pneumogastric—thus making a nerve circuit complete from an irritation starting in the ear. A young man presented himself at my office with the earnest request that I do something to relieve him of asthmatic attacks, to which he had been subject for two years. Seldom a week would pass without two or three paroxysms. He had tried all sorts of treatment, with only temporary relief in the way of alleviating the embarrassed respiration. Knowing the disease to be a neurotic one, and in all probability the result of an irritant, I made a thorough search for the exciting cause. The hearing in one ear was impaired, and this on examination was found to result from a mass of cerumen filling the whole external auditory canal. This was removed, and there was no more asthma for nine months, when the patient passed from under my observation. I have had two other cases similar to this one, and have notes on another. I cannot find in the literature of the surgeon general's library any cases of this nature, except one reported by myself a few years ago in a paper on asthma.

1016 Fourteenth Street, N. W.

A CASE ILLUSTRATIVE OF THE UNCLASSIFIED TROUBLES OF WOMEN.

By EUGENE COLEMAN SAVIDGE, M.D.,
NEW YORK.

The writer respectfully submits a concrete case bearing on the subject of his paper in the Medical Record of May 14, 1904, as above. In this case, the specialist concentrating attention on the local organs would almost have been under a logical necessity to operate. The synthetical point of view, however, reviewing obscure factors, not classified, and generally considered out of the range of gynecology, yielded not only a restoration to health, but also an offspring—the very result an operation would have made impossible.

Three years ago, a patient from a neighboring State was sent to me by the late Dr. Tucker. An eminent surgeon had positively condemned one ovary and tube to removal, and had expressed doubt about saving the other—a view in which six other men concurred. The patient was a young woman of thirty; six years married; no pregnancies; weight 115 pounds; highly neurotic temperament; with one prominent merely local symptom, viz., her menstruation occurred twice every seven weeks, was very profuse, put her to bed, and called for the strongest anodynes, even chloroform. These spells were always accompanied by diarrhœa.

Physical examination showed an infantile uterus in sharp anteflexion with a narrow os, with both appendages large and tender—as much so relatively as might be an "inside" orchitis, or an epididymitis, or a face after a bee-sting. With these symptoms—the orthodox indications for operation—what influenced my dissent from the eminent and multiple opinion? The following well-studied reasons:

1. These large and tender masses in the parametrium are frequently analogous with an epididymitis or a bee-sting—either of which conditions would look quite abnormal if submitted to pathological section. The writer believes that no surgeon can differentiate them off-hand from a knife-requiring pyosalpinx. They require detailed study.

2. This patient furnished a striking collection of "unclassified troubles." Her vasomotor system was unstable. The relational vasomotor effects were well marked. There were three quarts of urine passed in twenty-four hours, with a sp. gr. of 1.007. There were the icy feet and congested pelvis; the congested pelvis and the diarrhœa; the diarrhœa and the rapid heart action; the rapid heart action and the swelling thyroid, all accompanied by great venous relaxation at the various significant points already reported by the writer. In other words, this patient was in the condition patients are left frequently after operation. It was in toning up postoperative cases ten years ago that the writer first conceived the idea of applying the same measures *before* an operation that may be required after.

3. This patient had a profound anæmia, and had the usual hemorrhagic tendency to aggravate it. Complete evisceration does not always cure this bleeding. I have had patients with no womb to bleed from who suffered severe monthly hemorrhages from along the line of the bowels. It was also certain, considering the small womb, that this bleeding could be controlled, and the blood count brought up, by tamponade.

The treatment consisted in rest in bed, massage, muscle wringing, resistant movements, feeding, free diuresis, and tamponage at and between menstrual epochs, iron, intestinal disinfectants, and vasomotor constrictors. In forty days the patient had gained ten pounds, the urine had become normal, the pelvic swellings and tenderness had disappeared; so that it seemed then justifiable to do a simple dilation under primary anæsthesia. Three years later the patient was delivered of a healthy child. Her weight is now 145 instead of 115 pounds, the urine is normal in quantity and of a sp. gr. of 1.020, instead of measuring three quarts with a sp. gr. of 1.007, and for the two years preceding pregnancy menstruation was painless and regular. The patient is now a fully qualified wife and mother.

It will be noted that this patient had the beginnings of a classification in several different lines. Considering the kidneys, the thyroid, the heart action, the sudden air-hunger, and pupil dilation at a mere unpleasant thought, I feel sure that she would have died under operation. I therefore feel that the dissent and method outlined have saved two lives where there would have been but a tomb.

By a coincidence, a second woman, delivered of a child almost the same day, by Dr. Brown, of Montclair, N. J., had also been referred to me by Dr. Tucker about the same time as the first case. This second patient had likewise been condemned to salpingo-oöphorectomy by every gynecological authority, but showed many collateral troubles, the removal of which left her able to conceive.

CHRONIC RHEUMATISM.

THE conditions lumped together under this name constitute a very puzzling group. That they bear no close relation to acute rheumatic polyarthritis is fairly evident. In the *Bulletin of the John Hopkins Hospital* for July and August, an attempt at a scientific classification from both the clinical and pathological sides is made by Drs. J. C. Goldthwait and C. F. Painter. Their study of a large number of cases of non-tuberculous joint diseases, in the earlier stages, shows that at least five distinct types exist which require essentially different treatment.

Chronic villous arthritis (dry, hyperæmic, or relaxed joint) is a purely local process, usually occurring in the knee, with crepitus or creaking, and pain and tenderness on use. The joint is usually relaxed, and there is no natural tendency for the process to extend to other joints. The hypertrophied joint fringes present all intermediates between very numerous, very soft and vascular, small roundish delicate dendrites attached to the synovial membrane by extremely delicate pedicels, to one or two irregular, coarsely lobulated, yellowish fatty masses, 4 to 6 cm. in diameter, which are often glued down to the synovial membrane; the original pedicel is, however, usually distinguishable, composed of irregularly intermixed fatty and fibrous tissue with a cortical, very vascular, round-celled zone covered by a single-celled endothelial layer. The common characteristics of all the growths is the pedicellation and the extreme vascularity. More rarely occur fatty masses without fibrous admixture, or hyaline necrotic masses or connective tissue infiltrated with bone and cartilage cells. Treatment in the early stages consists in local stimulation, relief of any joint strain, and bandaging to steady the joint and limit motion. If the villous or lipomatous change is marked, the new formations should be removed by operation.

Atrophic or rheumatoid arthritis is of unknown causation, progressive for years with marked crippling, with at the beginning swelling, and very early atrophy, more prominent as the swelling subsides, visible at first in the cartilage, but ultimately involving the bone and soft structures. The blood shows no marked change. The capsule (fibrous and synovial), the cartilages, and the bones are involved. Joint swelling is due to synovial thickening and periarticular muscular atrophy. As a rule little fluid is present. During the more active stage the whole membrane is a good deal congested, and the hypertrophied villi are well distended with blood. The cartilage is thinned over its whole extent, becomes more or less granular and streaked, with in places eroded areas, through which the cancellated bone may be visible. The bone is also thinned, the intertrabecular spaces being filled with fat. The trabeculæ are diminished in number and size, and seem not to anastomose as normally. Many vessels are endarteritic. In places there is some round celled infiltration, but no other accompaniments of active inflammation. Radiographs show satisfactorily the general shrinking of the cartilage, the diminished density of the bone, and the thickening of the capsule with the villous enlargement of the membrane. Aseptic aspiration practised in ten cases proved sterile. So far, the blood in the acute stage has shown the hæmoglobin high, no leucocytosis, and a red count appreciably above the normal, contrasting with a low hæmoglobin value, higher leucocytosis, and a slight diminution in the red cells in acute rheumatism and other infectious cases. There is a reversal of the normal calcium-magnesium ratio, twice as much calcium being excreted as ingested. The treatment is rest, improved nutrition (with forced feeding, tonics, oil, a wholesome, generous diet in which meat is an important factor), free elimination with large amounts of water, and some alkali, such as sodium phosphate. Salicylates (5 grains once or twice daily) are at times beneficial; and locally, stimulation, encouragement of use, stimulant bathing, hot air, massage, and anything tending to improve nutrition. Resulting adhesions and deformities should be overcome.

Hypertrophic (osteo-) arthritis is a local or general process, with thickening of the edges of the articular cartilages into ridges or nodes (which, upon ossifying, interfere with motion), pressure-absorption of the cartilage, and sclerosis of the periarticular bone. The symptoms result largely from the mechanical limitation of motion, or pressure on the nerves. Etiologically, cold, exposure, strains, and injuries seem important. The blood shows no special changes. Where the cartilage shades off into the synovia there is apt to be congestion, usually with a ridge along this line. The cartilage is thickened, but preserves its glistening, bright appearance, and lacks erosions, which occur only as decubitus erosions, or dimples where osteophytes have chipped off. Pieces of cartilage may be found free in the joint. Large isolated cartilaginous spurs may project into the joint and villous hypertrophy, when present to any considerable degree, occurs near these spurs. Radiographs show a broader line of cartilage than in the atrophic type. A conspicuous feature in the picture is the irregular spur-like formation. Treatment consists in fixation to prevent irritation, with internal treatment to improve body tone and secure elimination. The disease is not usually progressive, and with proper treatment subsides, leaving little except the thickened cartilage and new formed bone.

Chronic gout is much less common, and consequently is less understood. The essentials seem to be sodium-urate deposits in the soft structures around the joint, with some bone absorption around the deposists, which are soft to pressure, movable in the soft structures, and without connection with the bone. Usually only a few joints show deposits. The shaft of the bone is frequently affected, and in fingers and toes an entire phalanx may be destroyed,

a little at a time, so that when seen the destroyed portion has a sharply defined, punched-out edge.

Infectious arthritis includes most of the cases of acute, inflammatory, or chronic rheumatism, and many septic processes. The symptoms may be due to toxins, or to the microorganism itself within the joint. Many or few joints may be affected, the disease in most cases reaching its height early without the further progress always seen in the atrophic form. If the organism itself is present the capsule may be much thickened with resulting disability, or marked destruction of tissue with pus formation may occur. The few cases studied, apparently gonococcal, showed in the acute stage a considerable excess of turbid synovial fluid, and a considerable and uniform thickening of the capsule and synovial membrane, which were densely infiltrated with round cells and with more leucocytes than in other forms.

The cartilage was not generally thinned, but at times eroded; there was no osteophytic enlargement; a good part of the joint cavity was frequently obliterated by firm adhesions, resulting in practical ankylosis. The radiograph shows absence of cartilaginous or osseous change, and the thickening of the capsule is easily visible. The infiltration and the effusion obscure the picture very much, causing a peculiar, more or less characteristic, blurred appearance. Leucocytosis, diminished hæmoglobin, and anæmia, with glandular enlargements, are noted. The existent septicæmia should be combated by tonics, forced feeding, fresh air, moderate rest of the joint, local antiphlogistics. When the organism itself is in the joint, when pus has formed, and when marked capsular thickening is in evidence, the joint should be opened and flushed out.

HEREDITY AND DISEASE.

Opinions have changed considerably with reference to the connection between heredity and disease. The belief was once universally current that most diseases could be transmitted directly from parents to children, notably tuberculosis, and that a child descended from tuberculous parents would inherit the tuberculous diathesis. Not longer ago than the year 1840 textbooks taught that consumption was an hereditary disease and writers of those days scoffed at the idea of its being contagious.

Mr. Clement Lucas, in the Wightman lecture, delivered in London a short time ago, considered the question of hereditary bias and early environment in their relation to the diseases and defects of children. The lecturer, while on the whole inclined to agree with the new views as to the transmission of disease, thought perhaps that the pendulum had swung somewhat too far in that direction and that scarcely sufficient attention was paid at the present time to the influence of heredity in the causation of some diseases. For instance, he does not think that the old observations as to the tuberculous types of patients are quite valueless, and is of the opinion that the pearly sclerotics, the sharp, refined features that may be seen in any wasting disease, may be produced by the tuberculous process. This may be transmitted to the offspring, so that after a few generations sufferers from the disease would have the type occurring in a healthy individual, and merely indicating a diminution of resisting power, perhaps to all diseases.

Malaria, again, formerly described as a climatic diathesis, is now known to be due to an organism, conveyed by the agency of mosquitos. Undoubtedly syphilis can be transmitted, although it has not been conclusively proved that the disease can be handed down beyond the first generation.

In the case of cancer, Lucas holds the view that there are distinct grounds for doubting the belief in the hereditary transmission of the disease.

There is, however, in the affections and abnormalities of the nervous system, the clearest evidence of the influence of heredity in disease. Fletcher Beach has stated that of idiots 51 per cent. have a history of mental defects in the family, 20 per cent. of epilepsy, and 16 per cent. of alcoholism. Gerrish has recorded an instance in which, through five generations, paresis of the anterior tibial muscle appeared between the ages of twenty-two and twenty-six. Deafmutism, judging from statistics, would also appear to be hereditary, and a large number of external pathological manifestations are also believed to be hereditary.

Notwithstanding the fact that heredity is regarded, and rightly so, as not having the preponderating influence in the causation of disease which it was once thought to exert, it may be questioned whether hereditary influence is not now too lightly regarded as a factor in disease. Tuberculosis is not directly transmitted, but the predisposition to disease is inherited, and the descendants of tuberculous forbears are more prone to contract the disease than those whose ancestors were free from the malady. Of course, the discovery that many diseases are caused by microbes and the likelihood that most organic affections originate in the same way, has unduly shaken our belief in the influence of heredity in disease. As yet, however, the proofs that heredity exerts no influence in this direction are not sufficiently convincing to overthrow completely the old views. The theory of heredity has been modified—not overturned entirely.

REPORT OF THE MARYLAND TUBERCULOSIS COMMISSION.

This report has just been issued and contains information of an instructive nature. Of course, much of the matter is already known to all, such as the nature of the disease, its prevalence throughout the world, the general mortality, manner of infection, prophylaxis, and treatment.

Respecting the prevalence and mortality from tuberculosis in the State of Maryland and in the city of Baltimore, the report states that, owing to the fact that no returns are required by law of existing cases of tuberculosis, it is impossible to obtain exact statistics as to the number of cases occurring yearly in the State of Maryland. It is believed, however, that there are at present at least 10,000 cases of tuberculosis in the State. In Baltimore, during the year 1902, there have been reported about 2,000 cases of tuberculosis. The figures of the commission bear out general statistics, which show the greater frequency of tuberculosis in the colored race. In 1902 there occurred in the State of Maryland 2,560 deaths from tuberculosis and during the same period there were 1,392 deaths from tuberculosis in Baltimore.

As to the economic effects of tuberculosis in Maryland, it has been shown by Dr. Price that the

average individual loss to a person suffering from tuberculosis was $741.64, and the average potential loss to the community resulting from the death from tuberculosis of a wage-earning male was $8,512.52. During the year from October 1, 1902, to October 1, 1903, there were 2,509 deaths from tuberculosis in Maryland. Of these 908 were of wage-earning males. From these figures it would appear that from the deaths of wage-earning males alone there resulted in one year a potential loss to the community of over $7,500,000, while the total potential loss from the 2,509 deaths can scarcely have been under $10,000,000.

The commission recommends the general adoption of prophylactic measures similar to those in force in New York which, it is declared, are the best that have yet been devised. The commission is strongly in favor of the sanatorium treatment of consumption, and is, further, of the opinion that if the State of Maryland undertakes to build sanatoria for the treatment of tuberculosis, every step should be taken to make such sanatoria the best in existence. With these ends in view, the suggestion is made that the Governor of Maryland appoint a commission for the specific purpose of considering plans, expenses, localities, and any other questions looking to the establishment of sanatoria for the care of cases of chronic tuberculosis and others for the treatment and cure of early and favorable cases of tuberculosis.

A part of the report is taken up with a consideration of the prevalence and distribution of tuberculosis in Maryland, while by far the larger portion of the book in which the report is contained is devoted to papers dealing with the recent exposition on tuberculosis, held in Baltimore, which was described at the time in the MEDICAL RECORD. The intense interest manifested in tuberculosis in this country at the present time is a healthy sign and argues well for the success of the crusade undertaken against the disease.

CRANIOTOMY ON LIVING CHILDREN.

THE moral status of this operation and the conditions under which it becomes permissible have always been mooted points among obstetricians. Discussions of the subject have been especially frequent of late, and though not many authors adopt so radical a position as Pinard, who, in a recent gynecological congress at Amsterdam, emphatically voiced his opinion of the undesirability of the operation by saying: "L'embryotomie de l'enfant vivant a vécu," still, the universal sentiment is in favor of conservatism in the employment of this extreme measure. Merkel, in 1883, stated that sixty-four per cent. of the craniotomies were performed upon living children, but this estimate would scarcely apply to the obstetrics of to-day. Symphyseotomy and, particularly, cæsarean section, have been developed to such a degree that they have become matters of daily experience, and through the improved technique and greater boldness of the operators many infantile lives have been saved.

Veit (*Münchener medizinische Wochenschrift*, September 20, 1904) takes a most decided stand and flatly states that mutilating operations upon the living child have no longer any excuse for existence. He confirms this conviction by the fact that in eight thousand deliveries conducted under his supervision in the clinics of Leiden, Erlangen, and Leipsic, the operation has always been avoided. When bad results follow symphyseotomy or cæsarean section they are, he says, always due to avoidable causes, chief among them being ill-advised attempts at forcible delivery, or too long delay before realizing the hopelessness of any but radical measures. These conditions should be met by a general adoption of the rule to transport parturient women of all ranks to suitable institutions as soon as there is any indication of impending difficulty. He believes that a large dose of morphine will enable the patient to be conveyed to a hospital without risk in nearly all cases, and then the proper operation can be safely carried out with little danger to the mother and none to the child. In his series of eight thousand deliveries, Veit performed cæsarean section twenty times and symphyseotomy six times. Of these twenty cases two mothers and two children died, figures which for the mothers alone compare favorably with those of craniotomy.

While this author may be somewhat extreme in his views, his statements are most suggestive. Undoubtedly what is needed is an earlier recognition of conditions in which the ordinary measures of artificial delivery are likely to be unavailing, so that more radical procedures may be carried out under circumstances favorable to their success.

CANCER RESULTING FROM EXPOSURE TO THE ROENTGEN RAY.

Two cases have recently been brought to public notice of malignant disease caused by the action of the *x*-rays. Early this month, an electrical engineer, formerly an assistant in Edison's laboratory, died of cancer of both arms. The early history of his case, as given by Allen in his recently issued work on Radiotherapy, is as follows: When first seen he had been working for three years making and testing *x*-ray tubes. A year after beginning this work he suffered from a condition of his hands resembling a severe sunburn which necessitated his stopping work for a few days. He then resumed his occupation and subsequently suffered from more pronounced effects, resulting in scars and contraction. For two months before coming under observation he had an ulcer on the back of the wrist and purpura-like spots were scattered over the skin of the arms, wrists, and backs of the hands. Several operations were performed, but the disease had become systemic, and the amputation only postponed the inevitable issue. The second case, fortunately less serious in its outlook, is that of a well-known physician and *x*-ray worker in Rochester, N. Y., who has recently suffered amputation of one hand and the greater part of the second in consequence of *x*-ray injuries. The patient was an enthusiastic *x*-ray therapeutist and diagnostician and neglected to shield his hands while working. Another prominent instance of the evil effects of the Roentgen rays was that of Dr. Blacker of England, who is said to have treated Edward VII. successfully for a rodent ulcer. He had an *x*-ray burn of the hand, which was neglected until the cancer which had developed had extended up the arm and invaded the axillary glands, and then it was too late for operation to be of any avail.

Early in the history of the radiotherapy of cancer, when cases were reported of the disease attacking the hands of those engaged in administering the *x*-rays, it was thought that they furnished the proof of the contagiousness of malignant disease; but the case of Edison's laboratory assistant, above mentioned, shows that it is to the irritation produced by the bombardment of the *x*-rays rather than contagion that the disease must be ascribed in those

instances. Why the rays should act now curatively now causatively is one of the mysteries of medicine, the elucidation of which, as Allen suggests, may lead to the discovery of the pathogenesis of malignant disease. But the immediate and important point is that they may act in a causative sense, and all workers with the rays should remember that they are dealing with a tremendous force—less immediately destructive than flame, but no less surely in many cases.

Safeguarding the Water Supply of Manhattan.

The question of the proper safeguarding of the city's water supply is steadily assuming more serious proportions. While the present conditions are undoubtedly in most respects fairly satisfactory, still even in the near future radical improvements will be needed to ensure security. The Chief Engineer of the Aqueduct Board in a report to the Aqueduct Commissioners urges the immediate building of an adequate filtration plant for New York City, and recommends that work on the eastern basin of the new Jerome Park reservoir be halted until the plans can be revised, so as to adapt it to the changes in the way of roofing, etc., required for this purpose. Pending action by the commission, work on this basin has been practically stopped.

Even more important, however, for the immediate present (since filtration is a matter of years) is the guarding of the Croton watershed so as to prevent contamination, and this problem each year is growing more difficult of practical solution. Throughout the entire section of the watershed there is much building going on, a fact which points to a constant increase in the population of the district and correspondingly augmented difficulties in preserving the small streams from pollution. Dr. Darlington, Commissioner of Health, has been inspecting this territory and expresses the view that the city must eventually control the source of supply by buying up the land in the watershed wherever there are buildings near the lower levels of the valley. This would be very expensive, but must ultimately be done if the water supplied to the boroughs of Manhattan and the Bronx is to be kept clean and wholesome. Eventually, however, no matter whence the water supply is drawn or how carefully the watershed is policed by the sanitary authorities, we must come to filtration, and the sooner this is done the less it will cost and the better it will be for the residents of the city, and especially for the visitors. About the efficacy of sand filtration there is no longer discussion; the experience of many European cities and of Albany, Philadelphia, and other cities in this country has amply demonstrated its value.

Radioactivity in the Waters of the Hot Springs Reservation.

Dr. Bertram B. Boltwood of New Haven, Conn., who was authorized by the Secretary of the Interior to examine into the radioactive properties of the waters of the Hot Springs Reservation, Ark., has completed his work and made an exhaustive report. This report is prefaced by an interesting account of the present state of our knowledge concerning radioactivity in general, and by a description of a new system of standardization devised by Dr. Boltwood. The author of the report describes in detail the methods pursued by him in his investigations, which were very exhaustive and covered a period of several months. The results of the electroscopic tests were quite satisfactory and demonstrated that the waters of the Hot Springs are radioactive to a marked degree. The properties of the emanation from the waters were found to be identical with those of radium emanation, but the boiling test showed that little or no radium existed in the waters. Dr. Boltwood, therefore, concludes that the radioactivity of the waters is due to a dissolved radium emanation (a gas) and not to the presence of salts of radium or other radioactive solids. The almost complete absence of radium salts was also demonstrated by an analysis of the tufa deposit formed by some of the springs on issuing from the ground, this analysis showing that the amount of radium contained in one hundred grams of the tufa was less than one-millionth of the quantity of radium associated with an equal weight of uranium in pitchblende.

News of the Week.

Dr. Bulkley's Annual Course of Lectures.—The sixth series of clinical lectures on diseases of the skin will be given by Dr. L. Duncan Bulkley at the New York Skin and Cancer Hospital, Second avenue and Nineteenth street, during the autumn and winter, commencing November 2. The clinic is held every Wednesday afternoon at 4:15 o'clock in the Out-patient Hall of the hospital, and in past years has always been very numerously attended.

A Chinese Woman Physician, Dr. Yamei Kin, was one of the speakers at the reception recently given in this city to the European delegates to the Peace Congress. She has also spoken on several other public occasions during the past two weeks, and in every instance has carried her audience away by her eloquence, her facile employment of English, and her charming personality. Dr. Kin was a ward of the late Dr. McCarthy, for over thirty years a medical missionary in China. She was graduated in medicine from the Woman's Medical College of the New York Infirmary in the early '80s, and has practised in Kobe, Japan, in Hawaii, and in California.

A Vacancy in the Open Division of the Bellevue Hospital Staff.—Doctor George B. Fowler, for many years Visiting Physician on the Fourth Medical Division at Bellevue Hospital, has resigned his position on the Medical Board. His successor will be appointed by the Board of Trustees of Bellevue and Allied Hospitals from members of the profession unconnected with any of the medical colleges, probably before the first of November. Applicants for the position should send their names to Mr. James K. Paulding, Secretary of the Board of Trustees of Bellevue and Allied Hospitals.

Medical Inspection of Schools.—The Board of Health has issued a circular to teachers in the public schools, giving them information regarding the work of the school inspectors. The circular states that the children of the household in which any contagious disease exists must be excluded from school until the termination of the disease and fumigation of the premises by the Board of Health. This applies to all contagious diseases except smallpox, when all the children in the house in which the case exists are excluded. A completed system of medical inspection of the schools has been established. A physician is sent daily to every school and the scholars are inspected as to contagious or infectious diseases. Trained nurses are assigned to the schools in the poorer districts. Children are made to keep themselves clean, and these nurses make home inspections. They show the parents the necessity of keeping their children clean and healthy.

The Repression of Quackery.—The Medical Society of the County of New York has issued a statement, giving reasons why so few of the multitudinous advertising quacks and abortionists in this city have been apprehended and published through the action of its officers. Lack of funds is pleaded as the most serious drawback, though the society has curtailed its scientific features in order to devote its funds to the suppression of quacks. It is also hampered, it says, by the difficulty of getting victims to testify.

Methyl Whiskey.—The investigations of the Coroner and of the Health Commissioner leave little room for doubt that some at least of the suspicious deaths in the west side region, known as the "Stryker's Farm" district, were due to wood alcohol poisoning. A fact which this occurrence has brought to light, which is "important if true" and there is little question that it is true, is that a very large percentage of the whiskey drank here, whether domestic or imported, is sophisticated, even if free from amyl alcohol adulteration.

Dividing the Fee in Chicago.—The Chicago Medical Society will, it is reported, take action on the question of the consultant giving a percentage of his fee to the practitioner recommending the patient. Some time ago a well-known physician of that city sent out to more than one hundred physicians in Chicago decoy letters purporting to come from a young country physician, saying he had a wealthy patient who needed special treatment along the line of the physician's work, and asking for a commission of 25 per cent. for referring the case to the Chicagoan. Out of the hundred physicians to whom the letters were sent, eighteen accepted the proposition. It is rumored that those men are to be disciplined for their action.

Titles of Officers of the Naval Medical Corps.—In his annual report Surgeon-General Rixey of the Navy calls attention again to the absurdity of his title, which should be, he thinks, Surgeon-Admiral, since an army title has no place in the naval service. Dr. Rixey's recommendation also embraces a change in the titles of subordinates. He asks that the medical director be called "Surgeon-Captain" and the medical Inspector "Surgeon-Commander," and similar changes be instituted on down through the naval medical corps.

Episcopal Hospital, Cincinnati.—A $25,000 addition to the Episcopal Hospital for Women and Children, Cincinnati, will be dedicated on November 17, the annual donation day of the hospital. Mr. Wm. A. Procter gave $10,000 toward this addition, and the rest was raised largely by the efforts of Archdeacon Edwards.

A Hasty Surgeon.—A well-known Paris surgeon was charged recently with having caused the death of an army official by leaving a rubber drainage tube in his abdomen. The post-mortem examination showed, however, that the drainage tube had not excited inflammation and was not the cause of death, and the accused was therefore acquitted. But he was immediately served with papers in a second case, charged with the same negligence, the only difference being that the second patient did not die. He contended, however, that his recovery was retarded and that his life was even yet in danger as a consequence of the absent-mindedness of the surgeon.

Dr. C. R. Holmes, who is a graduate and professor of otology at the Miami Medical College, has been elected to the chair of laryngology, otology, and rhinology at the Ohio Medical College, a place made vacant by the death of Dr. James Hyndman.

Association of Military Surgeons of the United States.—The thirteenth annual meeting of this association was held in St. Louis last week under the presidency of Medical Director J. C. Wise, U. S. N. The Enno-Sanders prizes for the best essay on military surgery were awarded to Lieut.-Col. William Hill-Clive of the British Army Medical Corps (first prize) and Lieut.-Col. Hathaway of the India Medical Service (second prize). The following officers were elected for the coming year: *President,* Surgeon-General Walter Wyman, P. H. and M. H. S., Washington; *Vice-Presidents,* Major Albert H. Griggs, N. G. N. Y., Buffalo, Brigadier-General Robert M. O'Reilly, U. S. A., Washington, Surgeon-General P. M. Rixey, U. S. N., Washington; *Secretary,* Major James E. Pitcher, U. S. V., Carlisle, Penn.; *Treasurer,* Major Herbert A. Arnold, N. G. Penn., Ardmore, Penn. The next annual meeting will be held at Detroit, Mich.

Mississippi Valley Medical Association.—The thirtieth annual meeting of this society was held last week in Cincinnati. Indianapolis was selected as the meeting place in 1905. The following officers were elected: *President,* Dr. Bransford Lewis of St. Louis; *Vice-Presidents,* Drs. Frank Parsons Norbury of Jacksonville, Ill., and J. H. Carstens of Detroit; *Treasurer,* Dr. S. C. Stanton of Chicago; *Secretary,* Dr. Henry Enos Tuley of Louisville.

Association of Erie Railroad Surgeons.—The thirteenth annual meeting of this association was held at the Colonial Hotel, Cleveland, Ohio, October 11 and 12, Dr. S. B. Hiner of Lima, Ohio, presiding. The following officers were elected for the coming year: *President,* Dr. F. A. Goodwin, Susquehanna, Pa.; *Vice-President,* Dr. M. S. Cramer, Ohio City, Ohio; *Secretary and Treasurer,* Dr. J. A. Allis, Montclair, N. J. The next annual meeting will be held in New York City.

The National Association of Colored Physicians.—This association, meeting in Lexington, Ky., closed its annual meeting Oct. 14 by selecting Richmond, Va., as the next meeting place and electing the following officers: *President,* Dr. John E. Hunter, Lexington, Ky.; *Vice-President,* Dr. R. E. Jones, Richmond, Va.; *Secretary,* Dr. John A. Kenney, Tuskegee, Ala.; *Treasurer,* Dr. A. L. Thompson, Memphis, Tenn.

Alcoholism from Patent Medicines.—Speaking at a banquet of the Catholic Total Abstinence Union of America in Hartford last week, the Rev. Father Walter J. Shanley, rector of the cathedral there, attributed the growth of intemperance among women to the presence of alcohol in patent medicines. He referred to the very high percentage of alcohol in a large number of patent medicines, and warned his hearers against the use of them. It is now in order for the religious paper to refuse the advertisements of these alcoholic poisons.

Telephones in Isolation Hospitals.—Dr. Edward Martin, director of the Department of Public Health and Charities of Philadelphia, has completed arrangements whereby a complete telephone system is to be installed in the Municipal Hospital for contagious diseases, with telephones in each ward, so that direct communication between without and within may be had. Hitherto the hospital, entrance to which is forbidden to even the nearest relatives of patients, has been connected with the world by a single wire, and communication was irregular and slow. With an exchange on each floor inquiries regarding the condition of patients can be answered speedily and satisfactorily.

Fire in a Hospital.—Fire was discovered in the dead room at All Souls Hospital, Morristown, N. J.,

one night last week. The Sister Superior was awakened at 2 o'clock by smoke which was pouring through the corridors, and found that several cots which had been put in the dead room were ablaze. The fire was quickly extinguished without alarming the patients, and the building was not injured.

Bright's Disease in Chicago.—According to the weekly bulletin of the Health Department, the first death from this affection in Chicago was recorded in May, 1864, but it was not until 1868 that deaths from the malady were reported in sufficient number to compute rates. In the annual report of the Commissioner for 1894, it was shown that the rate had increased 84 per cent. in twenty years, that is, in the decade 1885-1894, compared with that of the decade 1868-1877, and it was then said, speaking of the group of steadily increasing diseases, that the sanitary administration could do little to prevent the increase of Bright's disease and of diseases of the nervous system. The high tension of modern life with its besetting temptations to irregular habits and to excesses of various kinds is something the relief and remedy of which can come only through saner views and modes of life. The death rate of Bright's disease has increased upward of another 80 per cent. in less than a decade—that is, from 5 in the 10,000 of population in 1894 to 9.09 in 1903, or 81.8 per cent. in nine years.

Mortality in Michigan During September.—There were 2,635 deaths registered in Michigan during the month of September, representing a death rate of 12.7 per 1,000 population according to the State census of 1904. This shows a slight increase over the preceding month, which had a death rate of only 12.1, but is lower than the rate for September, 1903, which was 13.4. By ages, there were 608 deaths of infants under 1 year of age; 208 deaths of children aged 1 to 4 years; and 704 deaths of persons aged 65 years and over. Important causes of death were as follows: Tuberculosis of lungs, 155; other forms of tuberculosis, 37; typhoid fever, 63; diphtheria and croup, 36; scarlet fever, 6; measles, 4; whooping-cough, 4; pneumonia, including both lobar and catarrhal forms, 74; diarrhœa and enteritis of infants under 2 years of age, 318; cancer, 163; accidents and violence, 158. Smallpox caused 3 deaths during the month, 1 each in the cities of Petoskey, Jackson, and Flint. Two deaths were reported from tetanus.

More Hospitals Needed for the Navy.—Surgeon General Rixey, of the Navy, in his annual report, states that the future needs of the service will require hospitals at Charleston, S. C., Guantanamo, Cuba, and Olongapo, P. I. The failure of the navy medical service to obtain good and ambitious surgeons is attributed in part to the fact that assistant surgeons receive fifteen per cent. less pay when on shore than do those in the army. The naval hospital corps is reported to be in excellent condition, and it is recommended that it should be recruited to a strength of 1,000. It is also recommended that the number of pharmacists in the medical corps be increased to fifty.

"**The American Journal of Urology**" is the title of a new journal published by the Grafton Press, under the editorial management of Dr. Henry G. Spooner of this city. As the name of the paper indicates, it will be concerned exclusively with matters of medical import pertaining to the genito-urinary apparatus in both sexes. The first number, dated October, 1904, contains articles by Cathelin of Paris, Howard Kelly of Baltimore, and Winfield Ayres of this city, and a number of abstracts of recently published papers in American and European journals. The journal is very neat in appearance, and if the character of the contributed articles is maintained at the high level of those in the first issue, it is assured of a long and useful existence.

Purity of Food Products.—The Secretary of Agriculture will soon proclaim another series of standards for food products. The work of investigation and determination of what constitutes purity and adulteration in such products is being conducted by a committee representing the association of official agricultural chemists of the United States. The secretary of the committee is Chief Chemist Wiley of the Department of Agriculture. Two or three years more will probably be required to complete the list, as the work is so extensive that in spite of nearly two years constant work standards have been established for only comparatively few articles. The standards proclaimed last winter comprised meats and their products, milk and its products, sugar and its products, and spices and condiments. The additions now made to the list include meat extracts, ice-cream, grain products, fruits and vegetables, vinegar, fruit juices, fruit extracts, salad oils, salt, honey, tea, coffee, and root beer. Malt and spirituous liquors and carbonated waters were to have been included in the forthcoming proclamation, but so much difficulty has arisen over the dividing line between the purity and adulteration of these three subjects that they will be further investigated and proclaimed in the third installment, to be issued next spring.

An African Patron of Medicine.—Mr. R. R. Blaize, who died a few weeks ago in Lagos, was rescued as a child from a slaver, which had been captured by a British cruiser, and was brought up by the missionaries in Sierra Leone. He engaged in the Manchester trade and soon made a large fortune. He was liberal in all plans looking to the improvement of his race and was especially lavish in his gifts to the medical school, and it is believed that the bulk of his property has been left to promote the study of medicine in Sierra Leone and to aid students who might profit by a year of study in Europe.

A Faulty Diagnosis.—A young woman was seized with faintness in the street a few days since, and an ambulance was called to her relief. The surgeon promptly made a diagnosis of "drunk," and the unfortunate woman was taken to the police station. There the sergeant on duty took a little more pains than the young surgeon, and, finding the patient was perfectly sober, sent her to her home. She was on the way to her physician's office, when overcome. Ambulance surgeons have so much experience with "drunks," that they sometimes forget that a man with a fractured skull is a possible find, and that even young women who lose consciousness in the street are not necessarily intoxicated.

Dr. Wm. H. Taylor has been elected president of the Board of Trustees of the Children's Home, Cincinnati, to succeed Mr. Stetinius, who died some months ago. Dr. Taylor is professor of obstetrics in the Miami Medical College and on the obstetric staff at the Cincinnati Hospital.

Vaccination Decisions.—On October 10, Charles M. Rifer of Barberton, O., obtained an alternative writ of mandamus against the local Board of Education to compel the members to permit his four children to attend school. They had been barred, because they had not been vaccinated in accordance with a rule of the board.

On October 18, the Court of Appeals in this State upheld the constitutionality of the law which provides that a child who is not vaccinated shall not be

permitted to attend the public schools. The decision was in the case of Edward C. Viermeister, the court sustaining the decision of a lower court, to which Viermeister applied for a writ of mandamus to compel the Brooklyn school authorities to permit the attendance of his ten-year-old son. Viermeister attacked the law on the ground that it was in violation of that provision of the Constitution which provides that every child in the State shall be afforded an opportunity to have a common school education.

To Test a Cancer Serum.—The French Surgical Congress, in session this week in Paris, has voted to appoint a commission to determine the therapeutic value of Doyen's cancer serum. This action was taken after a heated controversy, and was accepted by Dr. Doyen on condition that the committee should not be one of investigation, but similar to that examining Pasteur's discoveries. Dr. Doyen is the surgeon whom Mr. Crocker is suing to recover a fee of 100,000 francs which he paid for the treatment of his wife by this serum.

The Pneumonia Commission of the New York Board of Health met for the first time on Tuesday evening of this week. Dr. Edward G. Janeway of New York was elected President and Dr. T. Mitchell Prudden of New York, Secretary. After a general discussion the commission decided to make a systematic study of pneumonia in New York, taking into consideration the frequency and variation of occurrence, evidence of communicability, mouth infection, seasonal relations, collection of statistics, and geographical relations. The commission was subdivided into a clinical committee and a bacteriological committee. The former is composed of Drs. Janeway, Osler, Musser, Billings, and Holt; the latter of Drs. Welch, Prudden, and Smith. Dr. Biggs will serve on both committees.

Raid on a Home for Epileptics.—An alleged "home for epileptics" was raided by the Chicago police a few days ago, and the books of the institution and the uniforms of women solicitors were seized. The raid was the result of an investigation made by Secretary J. A. Egan of the State Board of Health, who reported to the Chief of Police that the "home" was a fraud. The "home" employs twelve women solicitors. In making their rounds they dress in green and white gowns cut after the fashion of the costume of Sisters of Charity. The twelve solicitors are said to have collected from $150 to $200 a day.

A Practical Test of Food Adulterants.—Dr. Wiley, the chief chemist of the Agricultural Department, will resume his experiments on the effects of adulterated food with a class of twelve on Nov. 1. The experiments will continue eight months, during which time the twelve men will be fed at Government expense, with food in which at stated intervals adulterants will be secreted. A new lot of adulterants will be tried on this winter's class. They have not all been decided upon yet, but will include formalin, mostly used in preserving milk; two of the aniline dyes used in coloring food products, notably that employed to give the yellow tint of butter; sacharin, and copper, to which certain canned vegetables are indebted for their bright green color.

Dr. Albert A. Tennant has been appointed house surgeon to the Richmond, Va., Hospital.

Dr. J. G. Alcorn of Gallipolis has been appointed second assistant physician at the Ohio Penitentiary.

Hamilton, Ohio, Hospital.—Hamilton's new $125,000 "Mercy Hospital" will be formally thrown open to the medical profession October 19. All doctors in this and surrounding counties will be invited to a banquet in the new building. Drs. Zinke and Wolfstein, of Cincinnati, will be the chief speakers.

The Health Department of New York Awarded the Prize.—The announcement is made that the exhibit of the Health Department of this city at the St. Louis fair has been awarded the grand prize which is the highest honor in that class of exhibits.

Smallpox on the Canadian Border.—Reports received from Malone say that a serious outbreak of smallpox has occurred in the French Canadian settlement of that village.

Illness of the Dowager Empress of Russia.—The mother of the Tsar is reported to be ill in Copenhagen, her strength having been spent in many hours daily labor in fitting up Red Cross expeditions for Manchuria.

Home for Lame Children.—The directors of the New York Home for Destitute Crippled Children have empowered the president, Mrs. A. L. Erlanger, to purchase property on West Sixty-first street for the home. It is expected that the home will be opened about the end of this month.

Tuberculosis of the Nervous System.—Julius Grinker believes that tuberculosis of the nervous system is almost always secondary to tuberculous disease in some other organ. Brain tuberculosis occurs either as an affection of the membranes, or in the form of the so-called solitary tubercle—a misnomer, for tubercle appears multiple in many cases. The dura is but seldom the seat of tuberculosis and only when a disease process extends thither from the overlying bone or from the underlying soft membranes. The symptoms of tuberculous meningitis may be divided into general symptoms, caused by pressure, and focal symptoms, caused by direct implication of nerve-tissue. Headache is a very common symptom and may be caused either by direct pressure of the exudate upon the nerve filaments of the dura, or else indirectly by the fluid from within the ventricles. Experiment has shown that pressure in the brain of 70-80 mm. Hg., gives rise to pain, while a pressure of 80-100 mm. Hg. regularly gives rise to convulsions. Anæmia of the motor areas is probably the cause of these. The convulsions occur before the pulse becomes slow. A still greater rise of brain pressure causes a retardation of the pulse, which is probably due to stimulation of the vagus centre in the medulla. Under still greater pressure the pulse becomes rapid and irregular, due to paralysis of the vagus centre. This is usually of fatal omen. Respiration loses its regular rhythm rather early in the course of the disease. Other symptoms mentioned are clouding of the sensorium, pupillary anomalies, optic nerve derangements, rigidity of the neck muscles, trismus, grinding of the teeth, scaphoid abdomen, hyperæsthesia of the skin and muscles, exaggerated reflexes (in the beginning of the disease), the Kernig sign, and vasomotor disturbances. Most important of the focal symptoms is the cranial nerve paralysis. The typical cases are usually easy to diagnose, but the atypical cases are sometimes very difficult to diagnose. In such cases, Quincke's lumbar puncture is most useful. The fluid is cloudy in purulent meningitis. It may also be cloudy in the tuberculous variety. In the latter form the lymphocytes predominate. Streptococci and staphylococci may be found in purulent meningitis, pneumococci and the meningococcus intracellularis of Weichselbaum in epidemic cerebrospinal meningitis, and tubercle bacilli in tuberculous meningitis, and especially in the flocculi. As to the blood examination, it is said that there is a leucocytosis in the purulent variety and only slight increase of leucocytes, if any, in tuberculosis. In caries of the spine, if the spinal dura becomes affected at all, the tuberculous deposit occurs between bone and dura mater, producing a pachymeningitis.—*Illinois Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

FRENCH VISITORS—LUNACY IN IRELAND—BORDERLAND AND SUICIDE—HEALTH EXHIBITION—MIDWIVES' BOARD—FINSEN'S DEATH—A CASE OF PLAGUE—OBITUARY NOTES.

LONDON, SEPTEMBER 30, 1904.

THE long vacation closes to-day and next week the winter session opens. Several of the schools will maintain the tradition of the Introductory Lecture, but an increasing number are joining those which substitute other forms of celebrating the occasion, and some are content to set to work without any ceremony. The following week we are to have a visit from 140 to 150 representative French confrères—professors of the Paris faculty, physicians and surgeons to the Paris hospitals, and similar representatives of the Provincial schools of France. Visits to our chief institutions will be made and many lighter entertainments are being arranged. Of course, we could not omit a dinner to our guests, and this will be given at the Hotel Cecil. Private hospitality will be to the fore and I doubt not our confrères will feel they have done something to emphasize the *entente cordiale*.

The report of the Inspectors of Lunacy in Ireland, following closely that of the English commissioners, was circulated on Wednesday. There was an increase of 656 during the year, as against 508 in the previous year. The total increase for the year is 104 above the average of the last ten years, which was 552. The report is not pleasant reading, for it contains charges that at various institutions there were inefficient assistants, deficiencies in the staff, overcrowding, etc. Here is an example: The inspector of one district asylum regrets to find no improvement since his last report, in which he pointed out the overcrowding and deficient accommodation. Now he finds the same conditions. The floors of the sanitary blocks remain as before—full of holes and saturated with wet; the windows of the single rooms are boarded to prevent breakage, as no shutters have been provided; the walls are stained and dirty for want of paint and whitewash, or in other cases they are unplastered, and in others the plaster has fallen off; the furniture is deficient and many of the comforts usually found in our asylums absent. The overcrowding is manifest in the fact that there are 131 men and 25 women in excess of the number for which the institution is adapted. And yet the reporter remarks that "no steps appear as yet to have been taken to meet the pressing wants of the insane of the district, nor does it appear that the subject is under consideration." It is to be hoped that the attention of the Lord Lieutenant will be emphatically called to this report, for it is not the sort of thing to consign to a pigeon-hole in the office.

The difficulty of dealing with "borderland" cases was illustrated at an inquest yesterday, on a lady of independent means, aged 51. She had been a resident patient in a doctor's house for the last eight months, and had never threatened suicide. On Monday evening she went down to dinner, but was disagreeable, and went back to her own room, where she dined alone. Later a witness went to see her, but was ordered to leave the room. Still later the witness returned and found her crying and ill. The doctor then went and she told him that she had taken oxalic acid and was sorry for it. He thought from her remarks she did not intend to take her life, but only to make a commotion in the house. The coroner (Dr. D. Thomas) made some interesting remarks on such cases, which were much more difficult to manage than those which could be certified and put under restraint. He once held an inquest on a servant who killed herself to spite the other servants, after a quarrel about making the beds. In another case a lady said she felt impelled to throw herself under a motor car, and a friend took her home, where, as soon as left alone, she threw herself from a top window. In another case a young lady was convinced that angels were coming from heaven for her and took poison to assist. In the case before the jury, though the testimony was that she did not intend to commit suicide, the fact remained that she did so, though a short time previously she may not have thought of such a thing. It was stated that the chemist who sold the poison had no recollection of her, but he said he often sold 20 or 30 similar packets a day to persons who used it to clean hats or take stains out of clothes.

The Institute of Hygiene has determined to establish a permanent health exhibition, to form part of a scheme of popular teaching. Medical experts are to be in control and every exhibit is to be inquired into by a committee before being shown. Most of the spaces have been taken by well-known firms. The exhibition, which is to be opened to-day by Sir Joseph Fayrer, K.C.S.I., is to remain open daily throughout the year. No charge is to be made for entrance or for information supplied by the expert staff. The objects are officially said to be: to supply medical practitioners with the means of acquiring authoritative information on new products and appliances, and afford them a channel by which they may keep in touch with the advances made in all that relates to personal and domestic hygiene; to supply nurses with useful knowledge as to products and appliances for invalids; to supply the public, especially those interested in dietetics, clothing, appliances, and articles co-related with the health of the person or the home, with authoritative information as to their value and use.

The action of the Central Midwives Board continues to excite dissatisfaction and certain medical members are roundly denounced as traitors to the profession, while the desire of the women to control everything and to ignore medical men displays an animus equal to the ignorance which has been prominent. The Council of the Incorporated Medical Practitioners' Association, at its first meeting after vacation, has expressed the prevailing opinion in a resolution, protesting against the Central Board's decision to appoint non-medical women as examiners, thereby raising them so far as possible to the level of qualified registered practitioners. Perhaps other bodies may be roused from their apathy, though there is little hope of protests having any effect.

Inspector-General Duncan Hilston, C.B., M.D., who joined the service in 1860 and retired in 1897, has been appointed Honorary Physician to the King, *vice* Inspector-General McEwan, whose decease I mentioned a fortnight ago.

Professor Finsen's early death will be known to you as soon as to us and you know all about his achievements. Besides, the event scarcely comes within the purview of your London correspondent, but you may permit me to remark that it has unusual significance here on account of the interest of Queen Alexandra in his work, while the courage and cheerful fortitude with which he persevered in spite of illness inspired admiration and sympathy.

A case of plague was reported on Wednesday on a vessel which reached the Tyne from Hamburg, where dead rats were found during the discharge of cargo. The patient was removed to the floating hospital and the ship disinfected and allowed to leave, no other case having occurred.

Dr. Francis Bossey died on the 27th, at the ripe old age of 95. He took his first diploma in 1830 and his M.D., Glas., in 1832.

Another aged practitioner was Dr. Croker, of Belfast, who passed away on the 22d, within six weeks of attaining his 90th year.

Dr. T. Chaplin, who died last week, aged 74, formerly of Jerusalem, will be remembered by some of your traveled readers. He was physician to the leper hospital and held other important posts in Jerusalem, was on the committee of the Palestine Exploration fund, and had written on the local fevers. He took his M.D., St. And., 1858.

Dr. Archibald Hamilton, J.P., of Windermere, died on the 26th inst., aged 64. He was educated at Edinburgh University, and took his M.D. in 1861, in which year he also took the College of Surgeons license. He contributed to the *Edinburgh Medical Journal* some cases of amputation in which acupressure was employed.

Surgeon Henry Edward Raper has been cut off at the early age of 30. He died at the Royal Naval Hospital, Malta, of Mediterranean fever, on the 27th inst. He only qualified in 1897.

I regret to record the death of Edward D. Roberts, of Chester, L.R.C.P., & S., Edinburgh. He was found dead in bed yesterday at a Liverpool hotel, in which he had taken a room the previous night. His father, also a medical man, was mayor of Chester last year.

A CASE OF MENSTRUAL PRECOCITY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: At the meeting of the Omaha-Douglas County Medical Society, on September 27, Dr. M. J. Ford of this city presented to the Society a child of two years and four months with the following unique history: The parents are 33 and 32 years old and entirely normal. The mother says that she was sick all the time of her pregnancy with the child. She noticed at the time of the birth of the child, in 1902, that the genitalia were swollen. Her physician told her that it was simple swelling and would soon pass away. The child cried practically all its waking hours till it was six months old. On that day it began to menstruate, upon which it ceased crying and fell into its first peaceful sleep. It has menstruated regularly every 28 days since, except for two periods, when a cold was present. Warm drinks soon started it again. Exposure of the child to the Society showed a pretty child of normal face, but of unduly large limbs, and hips as well. There was an abundance of hair upon the pubes. The genitalia were very large; the mammæ were well developed. The mother said that the flow lasted from three to four days and was of fair quantity. The parents are well known to Dr. Ford and consulted him by reason of a pin having lodged in the child's throat. There is no suspicion of fraud.

Omaha, Neb. R. M. STONE, M.D.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Oct. 13, 1904.

A Case of Malignant Endocarditis.—J. F. Alleyne Adams believes that although malignant endocarditis most commonly occurs as a secondary infection, as in acute rheumatism, pneumonia, or septicæmia, it is recognized as sometimes occurring as a primary disease. Such a case is described in this paper. At any rate, the writer has not been able to discover any antecedent septic condition. All of the lesions found were apparently secondary to the endocarditis, with the possible exception of a nephritis. But of this there had been no symptoms, for the urine two months before the illness, and also at the beginning of the attack, was normal. There was a small abscess in the left kidney, but this was probably metastatic. If these renal conditions are considered secondary, as they doubtless should be, the case ought to be called one of primary malignant endocarditis. The writer adds that perhaps it would be better to describe it as a case of septic endocarditis, in which the origin of the infection was not discovered.

Examination of Pleural Fluids with Reference to Their Etiology and Diagnostic Value.—Percy Musgrave thinks that as a result of the study of a series of cases, he is justified in concluding that routine and systematic examination of pleural fluids will aid greatly in diagnosis and in determining the etiology of pleurisy. He speaks of various methods, of which cytodiagnosis is the only one that can be easily employed clinically, for the reason that animal inoculation, inoscopy, and culture methods can be employed in the laboratory only. The writer believes that cytodiagnosis is sufficiently accurate, especially when taken in conjunction with the history and bedside examination, and the physical and chemical properties of the fluid itself, to justify its use as a routine procedure. In some cases it has been not only of more than probable diagnostic value, but has given positive and signal results. The writer concludes that routine examination of pleural fluids will permit of the study of pleurisy with effusion with reference to etiology and diagnosis, as well as establish a basis upon which accurate prognostic statistics can afterwards be based.

New York Medical Journal, Oct. 15, 1904.

When to Operate for Appendicitis.—The rules which should govern the decision of this question are, according to S. C. Stremmel, the following: (1) The safest and best time to operate for appendicitis is during the interval. (2) The very early operation in the great majority of cases is the same as the interval operation. (3) If all cases were operated upon early or during the interval, there would be practically no mortality, if the operations were done by experienced surgeons. (4) When cases are not seen until late, or refuse operation, the Ochsner treatment should be given. (5) If, however, the patient gradually or rapidly gets worse, operation should be urged and such operation advised as will give the patient the best chance for his life at the time. (6) It is a serious reflection on the doctor who is caught with a moribund patient on his hands without having advised early operation. (7) In view of the fact that the mortality of late cases is from 14 to 20 per cent., and that the mortality of interval cases is from $^1/_5$ to $^1/_{10}$ per cent., it is self-evident that the interval operation should be the operation of choice.

Diffuse Dilatation of the Œsophagus Due to Cardiospasm.—This question is discussed in a paper by J. Tyson, E. Martin, and J. S. Evans, Jr. They refer to previous articles on the subject, and report two cases coming under their personal observation. In each instance a diagnosis was made of diffuse dilatation of the œsophagus with a spastic contraction of the cardiac orifice of the stomach. One case was practically cured by treatment, and the other partially relieved. The general symptoms pointing to the condition are the running out of food from the mouth when the patient is in a horizontal position, a varying dysphagia, regurgitation of food last taken; the introduction of an œsophageal bougie into the stomach without much difficulty, the suddenness with which the tube enters the stomach when the resistance gives way, the negative Rumpel's double-tube test, the inability to vomit, the absence of the second sound heard in swallowing, and the ability of the patient to overcome the difficulty by mechanical means. Not all of these symptoms were present in the second case, in which certain symptoms suggested a diverticulum or sacculation of the œsophagus. The cause of the trouble is to be found in lack of inhibition of the nerve force, which normally allows the cardia to open on the approach of food, and this may be due to vagus degeneration or reflex influences from distant areas. Of the cases mentioned, one (man) had a floating kidney, and the other (woman) had her dysphagia come on coincident with the cessation of menstruation. The rational treatment is the repeated overstretching of the cardia, in order to destroy its tonicity. Prognosis as to complete restoration of function is bad, but the cases are long, and death usually comes from intercurrent disease.

Medical News, Oct. 15, 1904.

The Mechanism of Exophthalmos.—W. G. MacCallum and W. B. Cornell have attempted to determine experimentally the mechanism of exophthalmos in cases of exophthalmic goiter. In these observations they have confined themselves to the study of the phenomenon produced in animals by disturbance of the circulation or by the stimulation of the cervical sympathetic, realizing, however, that it has not been conclusively proved that exophthalmic goiter is the expression of the continual stimulation of the cervical sympathetic. They conclude that: Obstruction to the outflow of blood from the veins of the orbit produces at once exophthalmos, which is relieved by the establishment of a collateral circulation. This process, however, is completed so slowly that in the meantime the orbital tissues, as well as the tissue of the face, become very œdematous, thus adding to the exophthalmos. Entirely independent of any circulatory changes is the exophthalmos produced directly by the stimulation of the cervical sympathetic nerve. This protrusion is due to the peristaltic contraction of the orbital muscle. The writers declare that although no certain conclusions can be drawn from these experiments as to the mechanism of the exophthalmos in Graves' disease, the possibilities are perhaps more closely defined.

A Factor in the Causation of Emaciation in Tuberculosis of the Lungs.—Harold M. Hays, in a series of experiments, has studied the activities of the digestive glands of tuberculosis patients, comparing them with the activity of the digestive glands of normal persons, and with the glands of patients suffering with malignant disease. It seems feasible, the writer believes, to take the salivary digestion as an index of the activity of the other glands of the gastrointestinal canal, first, because the secretory centers of the whole digestive system are so closely associated, and secondly, because a pathological state of the saliva means a profound alteration of the digestive system, for it shows less change in impaired digestion than does the gastric or pancreatic secretion. The writer has proved definitely that the saliva of patients suffering from pulmonary tuberculosis is greatly impaired in digestive power. Although the presence of a specific toxin of tuberculosis has not yet been proved to exist, still the alteration in metabolism in this disease appears to be due to the effects of some toxic agent which is either the specific toxin of tuberculosis or else is the result of the febrile process. All of the tuberculous cases examined had some fever. There was no fever present in the healthy persons examined or in the patients with malignant tumors. The writer suggests the possibility, therefore, that the diminution in digestive power is due to the presence of this febrile process. If absorption and assimilation of food do take place under the increased feeding in tuberculosis, it is probable that the digestive system of the patient accustoms itself to the increased toil and secretes more fluid, but fluid of a poorer quality. The alkalinity is greater than in the normal cases, but digestion is better when the saliva approaches the neutral point. In the patients suffering with malignant disease, the digestion was found to be better than normal, and none of these cases was an ulcerative one. As digestion is impaired in these tuberculous patients, it is comparatively simple to explain the loss of flesh and strength. As digestion is not so good, assimilation of food is more difficult. The metabolism of the body is altered and the organism has to draw on its own supply of fats, carbohydrates, and proteids. In the more chronic cases, the organism has become accustomed to the altered condition, and so the digestion is better than in the early cases.

American Medicine, Oct. 15, 1904.

Dust Disease.—Robert Kingman gives a very interesting note in regard to this affection. Some years ago he began to keep a medical scrapbook. The book which he used for this purpose was an old ledger that had been stored for various periods in several dusty attics and cellars. The writer handled the book only now and then, when he had the leisure to paste in the scraps. The intervening intervals might be several months, or even sometimes years. After such work he invariably experienced a train of symptoms, as described in Hessler's recent article on this subject. The dusty, musty odor of the book caused an immediate irritation of the nares and a bitter taste in the posterior pharyngeal wall. About 18 hours later began a subacute rhinitis, with furred tongue and a biting irritation of the nasopharynx; at the same time there were anorexia, fleeting nausea, flushing of the face, and an elevation of temperature of 1° or 2°, but with the sensation of considerable fever. General muscular soreness and marked depression also developed. These symptoms were at their height in the course of from two to four days, and then gradually subsided within the six or eight days following. After several attacks of this kind had been noticed, the writer learned to

anticipate one after the handling of the book, and he never was disappointed. Finally, he exposed the book to the sunlight for some time, after thoroughly beating it out and wiping the covers, binding, etc., with a mercuric bichloride solution, since which time it has been handled with impunity and without a single succeeding attack.

The Iodine Treatment of Suppuration.—Winfield S. Pugh calls attention to the excellent results obtained by the use of iodine in the treatment of suppuration. He reviews several classes of cases in which he has had gratifying success in the use of iodine. Scalp wounds, when first seen, are apt to be very dirty. The writer first cleanses the wound by means of a physiological saline solution, then thoroughly dries it. It is then swabbed with pure iodine, and the entire wound closed. In most of his cases he has succeeded in obtaining union by first intention. In cases of ulcer of the leg, at least 100 patients have been treated by the writer, by the iodine method. Many of these ulcers were exceedingly foul, being at times filled with pus and vermin, and in all cases one application was, as a rule, sufficient to rid the area of pus. Iodine acts not only as a germicide, but also as a deodorant. It also stimulates the formation of granulations considerably. Many large ulcers have been healed by this method, combined with rest in bed. In cases of inguinal adenitis, the area is opened up thoroughly, swabbed clean by means of dry sponges, and the iodine carefully applied to every part of the wound. In many of the writer's cases, union by first intention took place with but one application. Iodine exerts a most favorable influence upon vaginal discharges, particularly those produced by the gonococci of Neisser. In many cases the discharge ceases after a few swabbings of the cervix. Iodine has been applied to the uterine mucosa in the early stages of puerperal sepsis with excellent results. In the treatment of surgical tuberculosis, iodine is one of the very few remedies of value. The writer strongly advises its trial in all cases of suppuration.

The Molecular Concentration of the Blood and of the Urine, in Pregnancy, in the Puerperium, and in Eclampsia.—Ralph Waldo Lobenstine gives the following summary of his examinations: There is a marked diminution in the molecular concentration of the blood in pregnancy, the average freezing-point being 51° C. There is likewise a diminution in the concentration of the blood in the puerperium, the average freezing-point being 53°, but a rise over that of pregnancy. In eclampsia, the molecular concentration of the blood is not increased, the average freezing-point being 55°, the freezing-point of normal blood being 55° to 57° C. The urine shows no marked change in its freezing-point, either in pregnancy, the puerperium, or in eclampsia. The writer concludes that from cryoscopic findings there is no evidence of renal inactivity, nor of renal retention in eclampsia, *i.e.*, retention of the urinary products ordinarily supposed to be the cause of the disease, the products in question being crystalloidal in type. If there is renal retention, it must be a retention of either colloidal substances, which may come from either fœtus or mother, or of crystalline substances, too small in amount to affect the molecular concentration of the blood. Inasmuch, then, as the kidneys may be, negatively at least, ruled out as the primary etiological factor in eclampsia, and as a free interchange may take place between the fœtal and maternal blood, it would seem, both from clinical facts and experimental research, that eclampsia is an intoxication in which both mother and fœtus have a share, the pathological findings in both being due to the formation of multiple thrombi, with subsequent necroses. As yet it is not known what these substances are that give rise to the intoxication, nor what part the syncytium plays in their formation.

Journal of the American Medical Association, Oct. 15, 1904.

Spontaneous Tonsillar Hemorrhage.—L. S. Somers reports the case of a woman of seventy-five years, who, two days after the spontaneous opening of a peritonsillar abscess, had a severe bleeding from the tonsillar area. Pressure was made on the carotid artery of the same side. Pressure with two fingers of the unengaged hand was made over the tonsil, compressing the pillars, and a saturated tannic acid solution was poured into the mouth. Strychnine and ergot were given internally, and in about half an hour the bleeding ceased. Examination next day led to the belief that the main portion of the blood had come from the artery of the anterior faucial pillar, which had been eroded by the suppurative process.

The Relation of Cholelithiasis to Disease of the Pancreas.—E. L. Opie reports the case of a man of thirty-seven years suffering from lithiasis, accompanied by acute pancreatitis of the gangrenous type. Symptoms began seven months before admission to hospital, with pain in the epigastrium, accompanied by vomiting, which lasted two days. The pain disappeared and the patient was well for four months. A second attack began two weeks before admission, with epigastric pain, vomiting, and constipation; chills occurred. Exploratory laparotomy was followed by death four days later. Perforations were found in the transverse colon, posterior stomach wall and the duodenum, the latter perforations communicating with an abscess in the pancreas. Nine stones were found in the gall-bladder. In a second case, that of a man aged forty-seven years, symptoms began with sudden pain in the upper abdomen. A few hours later evidences of collapse set in, on the third day the temperature rose to 104° and death ensued. At autopsy, the pancreas was found much enlarged, and, save for scattered patches of relatively normal tissue, had a nearly uniform reddish-black color. The omentum was studded with foci of fat necrosis. The gall-bladder contained a single large calculus, about 2 centimeters in diameter. Opie lays down the general law that whenever a stone passes into the duodenum through the diverticulum of Vater, the pancreas is liable to injury in proportion to the size and character of the stone and the duration of its impaction.

A Simple Method of Cystoscopy.—The instrument described by M. C. Millet of Rochester is essentially an air-dilating cystoscope, in which water is used as the dilating agent. By attaching a fountain syringe filled with sterile saline solution to an instrument of this character one secures the advantages of water inflation, together with the possibility of quickly evacuating the fluid in case it becomes clouded, and replacing it with clear. The only interruption to the inspection is the few seconds required to empty the bladder. As soon as the clear fluid is again allowed to flow in, the examination can be resumed, the inflowing fluid transmitting the light as readily as if it were stationary. The stream is entirely under control; by means of the stopcock with which all air instruments are supplied, it is stopped or started; by raising or lowering the irrigator, its force is increased or decreased. Under the guidance of the eye the stream can be directed toward the suspected areas; blood clots and clinging mucus or pus may be dislodged, and the margins of ulcers thus clearly exposed. Tumors which appear as flat elevations on the bladder walls may be demonstrated to be villous by directing the stream against them or around their edges. Cloudy urine discharging from a ureter may obscure the field in that part of the bladder, but a single jet of clear fluid will clear that neighborhood, and the ureteral opening may be located before the next discharge of urine occurs.

Lithæmic Nasopharyngitis Due to Systemic Disturbance.—According to J. A. Stucky, many cases of nasopharyngitis are due to lithæmic conditions, and he considers the presence of indican, with uric acid excess in the urine, as an index of the condition. Treatment should therefore be directed to the constitutional state. Special attention should be given to clearing out the gastroenteric tract, and the author has found colon flushing with water and oil to be of special service. If there is much muscular tenderness or general malaise, strontium salicylate is given in ten-grain doses every two hours. Much meat, sweets, and salads must be avoided, alcohol given up, water taken freely between meals, the skin kept active, and exercise insisted on.

Experimentally Produced Genuine Epithelial Metaplasia in the Stomach.—G. Fütterer discusses the results of his experiments on rabbits, and as well the relations of epithelial metaplasia to carcinoma, as demonstrated by cases reported in literature. A lesion was produced in the stomach wall and the animals killed at varying periods thereafter. Five animals out of twenty-five survived the operation sufficiently long to allow of examination of the metaplastic formations; the other twenty survived more than one week, but sixty-nine other animals died within one week of operation. Concerning these five cases, the author makes the following statements: (1) All cases represented genuine epithelial metaplasias, as an ingrowth, an implantation, and a development from a germinal deposit could be excluded. There was no fistula in any of the cases. (2) In all the cases the metaplasia was at once followed by a down-growth. (3) This down-growth occurred under considerable growth pressure, as shown by the invagination of the muscularis mucosæ through the greater part of the hyperthrophic muscularis propria, and the invagination of the rest of that layer for quite a distance outside of the organ. (4) The metaplasia was followed by what we may call a practically unlimited proliferation of the squamous cells. (5) Such a down-growth and such an unlimited proliferation of cells are two principal characteristics of carcinoma. (6) We can here use the term metaplasia only for the metamorprosis of the columnar to the squamous cells, for there was no more metaplasia going on in the pegs, the products of metaplasia. (7) The epithelial cells nowhere broke through the muscularis mucosa, and the most characteristic peculiarity of carcinoma, the ingrowth into connective tissue, was absent. (8) What would have become of the strands, filled to the very end with squamous epithelial cells, if the animals had lived longer, cannot be said, and only further experiments can show it. (9) These are the first

cases of epithelial metaplasia, produced by experiment, on record, if we except a metaplasia in the bladder, which Lubarsch mentions, without describing it. It is to be remembered that structures considered to be characteristic of the ectoderm have been produced from ectodermal tissues, a fact which would make it impossible to uphold a sharp division of the germinal layers.

The Lancet, October 8, 1904.

Exclusion of the Intestine.—By this term B. G. A. Moynehan refers to the rendering inactive any part of the intestinal canal by surgical means. When entero-anastomosis is performed the length of intestine which lies between the two openings is "excluded." When the intestine is cut across, the distal end closed and the proximal end united to the side of the distal, the part of the gut which lies between the two points dealt with is "excluded." When, finally, the intestine is divided at two points and the proximal end of the upper and distal end of the lower are closed, left open, or united, the intervening portion is "excluded." The following varieties are recognized: (1) Entero-anastomosis; (2) the same with constriction by suture of the part distal to the upper opening; (3) unilateral exclusion in which the bowel is completely divided and the proximal end is implanted into the side of the distal, and (4) bilateral exclusion in which the bowel is divided in two places and the intestinal channel is restored, a segment of the bowel being left detached. Of this segment one end may be left open and stitched to the skin or both ends may be closed when a fistula exists in the bowel lying between them. The methods are described in full, illustrations being added. The general indications for these operations are as follows: chronic inflammatory disease; probably tuberculous, involving the bowel and leading to external fistulæ; in cases of inoperable carcinoma of any part of the large intestine, especially of the cæcum and ascending colon; and in rebellious cases of muco-membranous colitis. It will be recognized that unilateral exclusion, save in cases of disease affecting the lower end of the ileum, offers no advantages over lateral anastomosis, and that bilateral exclusion affords the best means of dealing with certain diseases, chiefly tuberculous and malignant, in the cæcum and colon, and with fistulæ between the small intestine and the bladder or vagina.

A Case of Pneumococcic Pyæmia with Recovery.—A. T. Davies and W. L. Brown report the case of a girl of eight years with pneumonia in whom there supervened: empyema, peritonitis, arthritis, and vulvitis. A rib was resected, the abdomen opened, and also the right knee joint. Pus from these two latter cavities contained diplococci of similar character to those found in the pus from the chest. The vulvitis came on only after the abdomen and it is assumed that some of the abdominal pus must have accidentally run down into the vulva. This latter complication yielded to simple antiseptic lotions. The child made a good recovery except for ankylosis of the knee joint. The authors give a statistical table of cases of multiple pneumococcus infection and analyze the statistics of the various metastases presented by the case.

A Case of Quadruplets.—A. C. Gowdey's patient was a woman of thirty-six years, a VI-para. None of her previous pregnancies were multiple. In two of them there had been seven hemorrhages. The first child was a female, weighed one pound and thirteen ounces and lived thirteen hours. Within twenty minutes after its expulsion two male and one other female children were still-born. The first presentation was transverse in the dorso-anterior position with hand prolapsed. It could not be replaced and forceps were applied to the breech. Of the three later presentations one was a breech, one transverse with hand prolapsed and the last a vertex. All were about the size of the first. Twenty minutes later the placentæ were delivered, the last one manually. Two were quite separate; the remaining two had their margins united, each having a separate chorion. The patient aborted after a pregnancy of five and a half months. There were no complications, and recovery occurred in a normal manner. The author quotes Fothergill as stating that quadruplets occur once in 387,000 deliveries.

British Medical Journal, October 8, 1904.

The Huxley Lecture on the Function of the Cæcum and Appendix.—Sir William Macewen states that the digestion in carnivorous birds and animals takes place principally in the stomach and small intestine, the cæca being rudimentary or absent; while in the herbivora the cæcum is enormously developed, and in the solipeds the cæcum is the chief digestive organ, the stomach occupying a secondary place. Man, if not an omnivorous animal, is at least a carnivorous and herbivorous one; therefore, by analogy, one would expect man to possess not only a stomach and small intestine, but also a cæcum—just as he has. As the vegetable food which he consumes is generally of the more tender and nutritive varieties, the cæcum is of moderate size only. The writer then cites cases which illustrate the fact that the arrest of the function of the cæcum results in disturbed digestion manifested in diarrhœa and in lowering of the strength, though these results may be modified by special diet. Certain movements have been noted in the cæcum, some of which originate in the appendix, the undulation running upward from the appendix, and causing the contraction of the cæcum. The writer believes that at the ileo cæcal valve there is a controlling reflex agency regulating the flow of partly digested food into the cæcum. It regulates the flow of material at a rate which enables the cæcum and its juices to deal with it. When this agency is interfered with, cæcal indigestion occurs, generally ending in diarrhœa of partly digested matter, but it occasionally leads to the massing of matter in the cæcum which causes constipation, with subsequent fermentive action of a kind which is apt to result in irritation of the mucous membrane and appendix. The exudation of the appendix and cæcum is augmented and diminished under certain circumstances. In the first part of the large intestine, and especially in the cæcum and appendix, the lymphatic follicles and the glands of Lieberkühn are very numerous and well developed. The succus entericus from the surface of the cæcum and appendix is a powerful aid to diges ion. Another element in the final disintegration of pabulum poured into the cæcum, is the micro-organisms. There is in the cæcum and appendix abundance of alkaline medium in which they can grow, and pabulum in the chyme for their development. They undoubtedly perform a part in disintegrating compounds which have resisted the action of the gastric and intestinal exudations. As to appendicitis, the disturbances of digestion are pre-eminent in its etiology. If stasis occurs in the contents of the cæcum, constipation which is so often a feature of appendicitis ensues. Later, fermentation of the fæcal contents with absorption of toxins and damage to the wall of the parts is apt to follow. Doubtless the appendix and cæcum are affected together. The writer shows how the standing lunch eaten against time while the mind is preoccupied is one of the surest ways of causing indigestion, and of finally causing cæcal and appendicular mischief.

On a Disseminated Form of Croupous Pneumonia in Children, or Primary Bronchopneumonia.—Samuel West declares that acute pneumococcal inflammation in the child often occurs in a disseminated form. The massive consolidation is the type seen in the adult; it often comes on without previous illness and is called idiopathic or primary. The patchy or disseminated form is the type in the child. It usually follows bronchitis, and is called secondary consecutive pneumonia, or more commonly bronchopneumonia. But a considerable number of the cases of bronchopneumonia occur without antecedent bronchitis. Post mortem shows, however, not massive consolidation but disseminated patches. There are, then, 2 types of bronchopneumonia in children. In the one the disease is of gradual onset, and preceded by some affection of the air tubes. The temperature is hectic in character, the course prolonged and interrupted by frequent relapses. The termination is by lysis. The mortality is high. In the other form the affection is of sudden onset and short duration, without any tendency to relapse. There is no antecedent bronchitis. The temperature is persistently high. The termination is by crisis, and the mortality is low. These two forms, the writer says, may be called primary and secondary bronchopneumonia, respectively. The secondary stands in close relation with bronchitis, the primary with lobar pneumonia. As to the bacteriology, Holt cites 19 primary cases, and the pneumococcus was present in all but 2; in 8 alone, and in 9 others in association with other bacteria. In 14 secondary cases, the pneumococcus was found alone in 2 only, and associated with other bacteria in 9. Pneumococcal inflammation is almost as common in the child as in the adult.

Functional Albuminuria.—Henry George Armstrong gives the following clinical picture of this condition: A boy or young man, the son of neurotic parents or parent, himself probably neurotic, gradually becomes slack and apathetic, his heart subject to intermittent attacks of dilatation and violent impulse, pulse frequent and varying in rapidity and tension, albumen in the urine during the day when in the upright position, but absent when in the recumbent position, urine of good specific gravity and without tube casts. The tonicity of the nervous system is upset. The inhibitory influence of the vasomotor system is interfered with, and the heart and arteries easily dilate. The arterioles of the Malpighian bodies are stretched and thinned and permit the percolation through them of a certain amount of serum. The most important point in the treatment is to persuade the boy and his parents that he has nothing serious the matter with him. Good air, good food, and good healthy exercise are the important factors. The prognosis is favorable.

Berliner klinische Wochenschrift, Sept. 26, 1904.

Does an Increase in the Molecular Concentration of the Blood Always Indicate Disease of Both Kidneys?—Loeb and Adrian report a case of carcinoma of the left kidney, in which the right kidney was practically normal, although the freezing point of the blood had been —.635° C. They ascribe the molecular concentration of the blood, in spite of the efficiency of the right kidney, as being caused by the suddenness with which the extra work was thrown upon it through the rapid growth of the tumor. They therefore conclude that unilateral kidney disease (excluding other causes and excessive size of the affected kidney) can exist together with increased molecular concentration of the blood, and that it is not justifiable in cases in which a lesion of one kidney can be proved, to conclude that the other organ is also diseased because the molecular concentration of the blood is raised.

Thermopalpatory Observations on the Temperature of the External Auditory Meatus.—Sommer says that the first author to report systematic temperature observations on the external ear was Winternitz. His figures showed that there was a regular afternoon rise in its temperature, which at night falls again. The author's own observations were made, not with the sluggishly acting mercurial thermometer, but with the new and very sensitive thermopalpatory apparatus of Herz. This shows only relative values, but is exceedingly delicate, and by its means the author was able to determine that the curve described by Winternitz does not regularly exist, but that there is a constant difference between the temperatures of the two ears, the left being invariably warmer. This fact is of interest in connection with the well-known greater activity of the left half of the brain, and speaks for a more energetic circulation of this side. The author believes that an extension of these observations will be found of use in the localization of introcranial lesions.

Münchener medizinische Wochenschrift, Sept. 27, 1904.

A Contribution to the Study of Acute Leukæmia.—Pfannkuch describes a case of this disease in which the blood picture was somewhat unusual. The patient, a man of twenty-three, died after an illness of acute onset lasting less than three weeks and characterized by vomiting, diarrhœa, cough, palpitation, general œdema, prostration, apathy, jaundice, dyspnœa, and albuminuria. The spleen was greatly enlarged, the liver less so, there was moderate swelling of the superficial lymph glands. On autopsy a general glandular enlargement was found, together with petechial hemorrhages in various organs. Microscopical examination showed a diffuse infiltration of many of the internal organs with lymphocytes, which were present in such numbers as to obscure the ordinary appearance of the tissue. The red cells numbered two and a half million, and the leucocytes one million. Smears showed a large preponderance of large lymphocytes (76.5 per cent), neutrophile myelocytes (10.6 per cent.), and polynuclear neutrophiles (12.2 per cent). There were no small lymphocytes nor eosinophiles. Many degenerated forms of lymphocytes were present, showing swollen or broken-up nuclei, and in some cases even not exhibiting any structure whatever. The case is very remarkable in presenting the lesions of an acute lymphatic anæmia (increase in the lymphocytes), together with those of a chronic myelogenous form (presence of large number of myelocytes), and the author considers it as possibly representing a primary mixed leukæmia.

Subjective Kakosmia.—Killian says that the condition of perceiving bad odors which do not exist in the surrounding air deserves the name kakosmia only so long as the course of the condition remains unexplained. Newer methods of rhinological examination have cleared up many of the formerly mysterious cases, and by detecting unsuspected suppurations, etc., about the nasal antrum, and sinuses, have restricted the field of purely subjective kakosmia chiefly to instances in which nervous lesions exist. The author reports two cases of patients complaining of the constant sense of a fetid smell, although no odor was noticeable to the breath exhaled through either the nose or mouth. Examination of nose, nasopharynx and mouth was entirely negative, but finally it was discovered that in each case the fossa of Rosenmüller on one side was the seat of the deformity known as Pertik's diverticulum. In the one case, this pocket was 2 cm. deep, and in both patients it contained a quantity of fetid necrotic material of the same sort as that composing the plugs occurring in the tonsillar crypts. Wiping out the diverticulum thoroughly with a cotton-tipped probe was sufficient to cure the disease.

Bronchoscopy.—Newmayer warmly commends Killian's method of bronchoscopy, which he has applied with success in ten cases. He makes the examination with the patient in the recumbent position, as this is not only more comfortable for the patient, but is also in many respects more agreeable for the operator. The head is allowed to hang over the end of the table and is supported and moved by an assistant in conformity with the operator's directions. The author first makes the attempt to introduce the instrument under cocaine anæsthesia, and resorts to a general anæsthetic only in cases where the local anæsthesia is found insufficient. If the procedure fails through difficulty in introducing the instrument through the larynx, lower bronchoscopy, performed through a tracheotomy wound, must be done. In none of the author's cases has the procedure given rise to any undesirable after-effects, though superficial abrasions of the mucus membrane do occur. His list of patients comprises three infants, of nine months, thirteen months, and two years, respectively, but the examination could be carried out without any especial difficulties. The author believes the method to be a most useful one for the removal of foreign bodies from the air passages, as it surpasses the ordinary means of physical examination and also skiagraphy in reliability, and at the same time affords the means of carrying out the removal of the object.

Deutsche medizinische Wochenschrift, Sept. 29, 1904.

Direct Bronchoscopy for the Extraction of Swelling Foreign Bodies.—Nehrkorn reports three cases in which beans were aspirated by children at play and became lodged in the air passages. In one immediate tracheotomy was necessary as soon as the child was seen, owing to the asphyxia caused by the increase in size of the foreign body; in the other two, bronchoscopy through the larynx was done, and the object removed by this means, though the patient had to be kept under general anæsthesia three hours in each instance before all particles could be gotten out. The author says that in such cases, after the initial irritation caused by the presence of the foreign body has subsided, a period of quiet without symptoms usually supervenes and lulls the observers into a sense of false security, which is followed twelve to fourteen hours after the entrance of the foreign substance, according to the rapidity with which it swells, by renewed asphytic symptoms,which steadily increase as the obstruction becomes greater and greater. Owing to the length of time required for the removal through the long and narrow tubes necessary for upper bronchoscopy in small children, the author counsels the immediate resort to tracheotomy and the use of the bronchoscope through the wound. Bronchoscopy should be carried out even in cases in which there is only suspicion of the presence of such foreign bodies as beans, etc., as they are sure to give rise to serious trouble and are rarely expelled spontaneously.

Suturing and Suture Material.—Mikulicz discusses the question of the purely technical aspects of surgery which have been allowed to fall somewhat into neglect in the last few years, during which the horizon of the surgeon has broadened in so many other directions, such as pathology, bacteriology, physiology, etc. One of the most important features in a good technique consists in the art of suturing properly, and this, of course, involves the proper choice of suture material. Silk and vegetable fibers are the most prone to give rise to infection in regions where the entire absence of germs from the wound cannot be guaranteed; wire of various metals is strong, antiseptic and lasting, and silk-worm gut also has these properties, but these materials are not always suitable for buried sutures. Catgut and other animal material, such as reindeer sinew, by careful preparation can be made perfectly aseptic, and in many ways they are an ideal suture material, but their rapid absorbability unfits them for many uses. Under the author's direction, tanned catgut has been prepared by winding the threads on glass plates and immersing these for twenty-four hours in a 5 per cent. aqueous infusion of quebracho bark and then sterilizing them by Hofmeister's method. Treated in this way, the material gains somewhat in tensile strength, and its absorption is delayed so that it remains in the tissues unchanged for at least four weeks, and is not wholly absorbed until from eighty to ninety days. The author has used this material in a number of cases for abdominal suture, particularly after gastric and intestinal operations, and has found it very satisfactory, though it is too early to express a final opinion on its merits.

Observations on the Effect of Radium on Embryonal and Regenerative Development.—Schaper exposed the ova and embryos of frogs and other animals to the rays and emanations of radium. It was found that the effect of this agent was to inhibit cell division as well as embryonal differentiation and growth, and that regenerative processes were similarly affected. These effects became manifest after a latent period varying in duration according to the intensity of the rays and the degree of development of the animal.

French and Italian Journals.

The Development of Hysteria in Childhood.—Benjamin Weill declares that hysteria in childhood is not rare, but it increases in frequency with the approach to puberty. The most generally admitted predisposing cause is "hereditary taint." In most cases there are disturbances of nutrition.

These disturbances are not characteristic of hysteria alone, but are also observed in other neuroses. There is noted, for example, an increase in uric acid and of the xanthin compounds, and of urobilin, on examination of the urine. In the cases of hereditary hysteria of childhood, there are two elements, the somatic—non-specific—showing itself in a general or localized excitability, and the psychical element, characteristic of hysteria. The same manifestations, provoked first by causes purely somatic, may be prolonged or recalled by a psychical cause. In the absence of heredity as a factor, hysteria can appear as an isolated phenomenon, generally of epidemic origin, and in a condition of weak resistance, such as the age of puberty. In these rare cases, an intense emotion may provoke this condition. This condition is the more serious, as the age at which it appears is more advanced, and thus the mental state of the patient is more complex and more coördinated. Early symptomatic treatment in this condition is necessary, as well as attention to external and alimentary hygiene, and to psychical conditions.—*Revue Française de Médecine et de Chirurgie,* September 12, 1904.

Abscess of the Liver in Typhoid Fever.—A. Guinard calls attention to the rare occurrence of large liver abscesses in the course of typhoid fever. He gives the history of a patient who developed typhoid after eating oysters. The patient was forty-three years old, and had always been in the best of health. On October 21, 1902, he took to his bed with typhoid fever. Hemorrhages appeared within a week. About the middle of November abdominal and precordial pain developed, with nausea and vimiting. On the first of December, the liver was noticed to be increased in size. Three weeks later the patient had cold sweats and the face expressed great pain. On the eighty-first day of the illness, an exploratory puncture was made. Pus was found. On the next day laparotomy was performed. With the thermo-cautery about 2 cm. of thickness of the hepatic tissue was incised, and thick pus flowed out of the wound in abundance. On the days following, the found did well, but on the seventh day, the patient began to fail rapidly and death supervened. The pus from the abscess revealed the presence of the typhoid bacillus. The writer believes that if intervention takes place before the liver is profoundly involved, that there will be a chance for the patient.—*Revue Française de Médecine et de Chirurgie,* September 12, 1904.

Syphilis of the Circulatory System.—Pétrini de Galatz believes that syphilis of the circulatory system is far more common than is generally thought. Many cases of cardiopathy, of aortitis, of hemiplegia, considered by the physician to be of rheumatic nature, ought to be treated with syphilitic remedies. In these cases syphilis ought always to be thought of. It is among syphilitic cases who have not been properly treated that these circulatory affections are encountered; mercurial inunctions have not been persevered in. The writer declares that injections of mercury will cause these cases to be more rare in the future. Intravenous injections of sublimate in severe cases of syphilis are preferable, especially when vascular alterations are determined. The writer then refers to his personal experience in the treatment of such cases.—*La Presse Médicale,* September 21, 1904.

The Way by which the Virus of Rabies Reaches the Salivary Glands of the Dog.—Bertarelli believes that the virus of rabies must reach the salivary glands by either the blood, the lymphatics, or the nerves, and the last method he considers to be the most probable. He has shown that if the nervous path is interrupted the submaxillary gland never is virulent; if the blood vessels are interrupted and the nerve paths are not, the glands are always virulent. Hence the virus must come through the nerves. At the same time, the injection of the virus into the salivary glands does not give rabies to the dog, and that from a salivary gland of a rabid dog injected into the gland of a healthy dog does not make him rabid. He suggests that in some animals the salivary secretion counteracts the virus.—*Rivista Critica di Clinica Medica,* September 3, 1904.

Contribution to the Study of Chyluria.—Umberto Gabbi writes of non-parasitic chyluria: The symptoms are milky urine, albuminous and capable of coagulation, through containing the materials of fibrin, with a sediment containing leucocytes and fat. The fat is not the result of fatty degeneration. It does not come from a lymphatic cyst. The patient whose case he describes had had several attacks of abdominal and lumbar pain, with swelling of the abdomen and presence of milky urine, which formed coagula after it was passed. The urine contained fat, white blood corpuscles, albumin, albumose and peptone. The fat was present in fine emulsion and in considerable quantity; the urine coagulated both within the bladder and after emission. Cystoscopy showed the mucous membrane of the bladder and ureters to be normal. The right kidney was enlarged and tender, and the anthor believes that the chyluria was of renal origin.—*Il Policlinico,* September, 1904.

Glycogen in the Treatment of Hyperacidity of the Stomach, and Dyspepsia.—Léon Meunier, in his investigations along these lines, has observed that the digestion of amylaceous foods—their transformation into dextrose, is very imperfect in patients afflicted with hyperacidity of the stomach. Meunier has also been struck with the fact that the emaciation in these patients seems to increase proportionally as the amount of sugar in the gastric juice decreases, and he has tried to combat this emaciation by the employment of some form of sugar to be given in the food. After numerous experiments, he has concluded that glycogen, of all the substances that he has employed for this purpose, gives the best results. He cites various cases in which the emaciation continued, in spite of the fact that the patient was taking 4 liters of milk a day, the amount of lactose in this quantity of milk being about 150 grammes. But these same patients, after having the identical diet, except the glycogen, which was added, have begun to increase in weight. About thirty patients have been treated by this method, and the increase in weight has been observed in each case. These results have been tested by other physicians. Glycogen, besides having a favorable influence upon nutrition, also acts as an antiferment in these cases, and is especially valuable in cases of hyperacidity with stasis. It also seems to have a direct action upon the secretion of pepsin.—*Revue Française de Médecine et de Chirurgie,* September 26, 1904.

Artificial Dilatation of the Cervix in Obstetrics.—Réne Koenig reviews very briefly several cases of eclampsia in which dilatation was employed. In one case only was the dilatation complete, for he feared the results of this maneuver. The writer emphasizes the danger of this proceeding, and declares that it is in such cases that multiple lacerations occur. He concludes by saying that it is premature to formulate a definite opinion concerning a method for which the operative indications are not yet clearly established. Nevertheless, in respect to very rapid dilatation, he believes that the modified dilator of Bossi has a place in the outfit of an obstetrical clinic, or in that of a specialist in obstetrics; but he does not believe that it ought to be found among the instruments of a general practitioner. When the cervix is effaced and slightly resistant, the Champetier bag may be used, or the method of unilateral dilatation. If the cervix is still of almost normal length, anterior vaginal hysterotomy will be preferable. The writer believes that rapid dilatation should be employed only when the life of the mother of the child is in immediate danger.—*Revue Médicale de la Suisse Romande,* September 20, 1904.

Contribution to the Study of Suppurative Monoarthritis of Puerperal Origin.—N. Pasturel calls attention to the fact that, as a rule, streptococcic septicæmia is the cause of suppurative arthritis which develops during the puerperium. The uterus is the point of departure, and the joint troubles are caused by metastases. But besides this class of cases, in which septicæmia gives rise to multiple suppurative foci in the joints and in the various organs, suppurative monoarthritis may develop as a local affection. The etiological and pathological conditions in these cases are the same as those of puerperal infection in general. Suppurative monoarthritis can be compared with suppurative pleurisy of puerperal origin. The knee, especially, is most often affected. The symptoms, course, and prognosis, vary according to the case. Death may take place from septicæmia, or from complications to which the articular focus has given rise. If recovery takes place, ankylosis should be guarded against. Aside from the general therapeutic indications of puerperal infection, arthrotomy, practised at an early period is justifiable in cases of suppurative monoarthritis. Recovery is common when the infection is localized. A satisfactory restoration of the movements of the joint may also be hoped for.—*Gazette des Hôpitaux Civils et Militaires,* September 24, 1904.

Contribution to the Pathological Histology of the Gasserian Ganglion.—Rocco Caminiti has examined a considerable number of cases of trigeminal neuralgia and other nerve lesions, with reference to the changes in the Gasserian ganglion and other parts of the nervous system. The patients were all over thirty-five years of age. He noted great variety in the form and size of the cells; difference in the depth of staining; partial destruction of the cell body and chromatic substance; changes of the body into tiny granules; thickening of the chromatic substance in some cells around the nucleus and at the periphery; displacement of the nuclei from the center of the cells; a large amount of yellow pigment; some empty cell capsules. The author concludes that the many changes in the Gasserian ganglion are in no way characteristic of trigeminal neuralgia. Many of them are found in senile cases in normal subjects, as well as in other nervous diseases. At the same time the neuralgia seems to result from a sclerosis of the ganglion.—*Giornale della Associazione Neapolitana di Medici e Naturalisti,* March-April, 1904.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Twenty-first Annual Meeting Held in New York City, October 17-20, 1904.

WILLIAM H. THORNTON, M.D., OF BUFFALO, PRESIDENT, IN THE CHAIR.

MONDAY, OCTOBER 17—FIRST DAY.

Meeting of Council and Fellows.—The meeting of the governing body of this association convened in the New York Academy of Medicine at 1:45 P. M.

President's Address.—Dr. THORNTON of Buffalo made the request that the standing committee be more active and energetic in assisting the Chairman, and also that the officers of the various county associations be more careful in seeing that the annual dues were collected. The financial condition of the Association was better than it had been for a number of years past. When considering the various questions that would be presented at this meeting, he asked that the gentlemen would bear in mind the honor of the Association and the good of the entire profession of the state. He asked the influence and aid of the publishing committee. He pleaded that each member would do all in his power to increase the membership and to make all reasonable effort to promote and preserve harmony in the Association.

Treasurer's Report.—The total expenditure during the past year had been $11,717.20, of which $744.05 had been for legal expenses. The balance on hand showed $4,073.16, a most encouraging report.

Committee on Legislation.—Dr. E. ELIOT HARRIS said that there had been four important bills that had occupied the attention of this committee, three in this State and one in Washington, D. C.

Report of Committee on Conference.—Dr. E. ELIOT HARRIS, Chairman of this committee, briefly outlined the history of the attempt at amalgamation of the New York State Medical Association and the Medical Society of the State of New York, and said that they started out with the idea of mandatory legislation, and an impartial lawyer had been employed, who told them that this was out of the question, but that a permissive act might be obtained. Several conferences followed with the idea of union in view. What the State Association stood for mainly was always clean medical literature, clean advertising, and reliable data regarding physicians. The question of sentiment they were willing to waive in order that they might obtain the principles the Association had worked out and fought for. The agreement was ratified at a special meeting. The plan of union was defeated because the lawyers called attention to the fact that it would be an illegal meeting, unless each member received a personal notice, as required under the present by-laws. The present by-laws did not provide for giving notice of any meeting at which action might be taken interfering with the members' rights; therefore, in issuing a call for such meeting a personal notice must be served on each member. Of course, such a thing was out of the question. Therefore, the attorney started to draw up a modification of the by-laws so that a legal meeting might be held. No consolidation of the two societies could take place until that was done.

After strong opposition on the part of some members, and heated argument in favor of it by others, it was moved, seconded and passed that the whole matter be left on the table for another year.

Officers Elected.—*President*, Dr. J. Riddle Goffe of New York; *Vice-President*, Allen Arthur Jones of Buffalo; *Treasurer*, Dr. F. A. Baldwin of New York City; *Secretary*, Dr. Charles I. Redfield of Middletown.

SECOND DAY—TUESDAY, OCTOBER 18.

Conservatism Versus Early Intervention in Simple Dystocia.—Dr. WILLIAM J. MEYER of White Plains read this paper. He confined his remarks to observations of such cases as were frequently encountered, cases of dystocia which resulted from inadequate expellent forces. There were two primary conditions to be considered, those in which the expellent forces were deficient, and those where the resistance offered was abnormal and, therefore, pathological. The first class was due to uterine inertia. He believed that we were all too eager to avail ourselves of the conservative treatment of such cases, and that now was the time for some one to champion early interference. Many permitted themselves to overlook the significance of a late labor. Uterine inertia, as well as cervical rigidity, may exist for days, and these conditions were allowed to exist because physicians refrained from the use of forceps. He condemned the indiscriminate use of forceps, but he did not believe that we were justified in condemning their use because of the ignorance of a few. In his experience, the careful application of forceps was not followed necessarily by perineal lacerations. He did not know of any physiological reason why one should not interfere with the obstetrical forceps in such cases. What he claimed for the practical application for the forceps was based upon an experience with 186 cases of simple dystocia, which occurred in his practice during the last five years. Among these cases he had had no laceration of the perineum or postpartum hemorrhage. An appreciation of the use of antisepsis was very necessary. In cases of rigid cervical canal, he advocated the manual dilatation of the os, and this had been the treatment that he had employed during the past five years, and his results convinced him of the wisdom of it. He never allowed his cases to remain in labor beyond seven hours without interference; when early interference was made complications became much less. He claimed that the social, mental and moral conditions of later life were often due to stupid conservatism in obstetrics.

Dr. EVERARD D. FERGUSON of Troy commended the paper which made the principal point of manual dilatation in those cases in which there was failure of the cervical canal to open under contractions of the uterine body. The interference should be manual and not instrumental. Of all instruments of terror, the mechanical dilators made of metal, such as Pozzi's, were most to be deprecated. With the finger one could estimate and determine exactly what progress was being made. With clean hands and a clean vulva, the risks of manual interference were reduced to a minimum. In cases calling for interference, such as placenta prævia, he had never resorted to any instrument further than his own hand to aid in delivery. In fact, the hand might take the place of other instruments as, for instance, preliminary to dismemberment of the child.

Dr. BERNARD COHEN of Buffalo for many years had made use of manual dilatation in rigid cervix; this also gave him information as to why such a condition existed. If careful, one could preserve the bag of waters. After having dilated the cervix he believed that the head would exgage, and therefore, it would not be necessary to apply the forceps; the head would come down if left alone. Morphine and quinine as an oxytocic might be given. The general practitioner should become more acquainted with the axis traction forceps. He did not agree that one should interfere after two or three hours, but after six hours of labor. He emphasized the importance of the judgment of time in the use of forceps, i. e., the "obstetrical moment" or the right time of applying forceps. In his experience with 2,500 cases, he found that he had torn one out of every seven perineums, and one out of every five cervices.

Dr. JOSEPH B. COOKE believed that with the aid we have from aseptic and antiseptic methods, we should become something more than mere midwives, and he agreed in the main with the reader of the paper. He never used the forceps to dilate the cervix, but invariably used the fingers until it was completely dilated or paralyzed. When forceps were applied, the patients were always anæsthetized to the surgical degree. The "obstetrical moment," he believed to be very important; there was such a time. After

that moment had passed the tissues became infiltrated and would not heal so well. He deprecated the removal of the forceps when the head was on the perineum or partly through the vulva; they should not be removed, but allowed to fall off after expulsion of the head.

Dr. Benjamin W. Stearns of Binghamton advocated the administration of six grains of chloral hydrate, one-half a drachm of viburnum compound, and two grains of quinine, given every twenty minutes, to relax a rigid cervix. The giving of chloral did not contraindicate the administration of chloroform later.

Dr. Meyer said that his paper was written entirely in reference to cases of delayed labor.

Asthma and Its Relation to Environment from Blood Etiological Standpoint.—Dr. George N. Jack of Buffalo said that he had demonstrated in previous papers that asthma or the asthmatic dyspnœa was not a disease by itself, but only a symptom, or an abnormal biochemical and complex pathological process, usually originating in the intestinal canal, through a long-standing toxæmia, with faulty absorption and metabolism producing lymphogenous chyle, that generates an unstable blood, characterized by its extremely varied, numerous and alarming paroxysmal, morphological changes often alternating between a lymphocytosis, an intestinal toxemic leucocytosis or an anæmatosis; accompanied anatomically by a hyperplasia of the lymphatic and glandular structures and clinically by dyspnœa. The anatomical construction of the air tubes was such that they could not contract spasmodically to interfere with the ingress or egress of air in the lungs; consequently we are compelled to regard the ancient spasm theory as a deception, and thus a new proposition confronted us, namely, asthma and its relation to environments from a blood etiological standpoint. Asthma was the outcome of a well defined pathological process that had been developing for months, years or generations. The asthmatic was always prepared for an attack, and the conditions above mentioned produced a variety of circumstances that individualized each asthmatic and rendered him susceptible to a certain environment. He stated that the asthmatic was a human barometer and thermometer, which, together with his actinic, hydraulic and magnetic properties, rendered him susceptible to and affected by every conceivable environment. He stated that there were, therefore, two classes of environments as regarded the asthmatic, the favorable and the unfavorable. All environments came under these, climatic, thermic, actinic, meteoric, humidity, altitude, telluric, topographic, latitude, longitude, rest or jarring, dust and fumes. The asthmatic was so sensitive that he was hourly elated or depressed by them. He related the case of a man with the usual pathological conditions who was put on correct diet and appropriate treatment several weeks before his customary attack appeared, who soon showed remarkable improvement. However, two days before the date of his usual attack, which had been appearing for the past twenty years, he presented himself with a coated tongue, urine loaded with indican, almost black, blood loaded with leucocytes and eosinophiles, abdomen distended with gas, water bags under his eyes, swollen fingers, and evidences of general lymph stagnation. Most rigid prophylactic measures were instituted and won the day; the patient escaped the asthmatic attack which had appeared every August for twenty years, and had continued until the following May or June. The depression and disturbed digestive functions due to prolonged heat, together with its relaxing influence upon the blood and lymph vessels of the skin and mucous membranes, were conditions which encouraged stagnation of lymph throughout the whole body. The effect of the heat on ingested food and water were also etiological factors. When the subject thus affected by the heat was exposed to the opposite environment of a cold, damp autumn night, the tissues and capillaries being relaxed, the blood, missing the effect of sunlight, resulted in an increased accumulation of products to be gotten rid of. In the recumbent position, gravity aided the flow of blood to the lungs and glands in the air tubes, and as a result the attack of asthma came on. Dust and fumes were at most only aggravators, and never causes, of this condition. The pollen dust asthmatic was rarely met with. Damp, swampy and illy-drained districts afforded unfavorable environment for the asthmatic, as the blood, lymph and digestive ferments would undergo precipitation and disintegration. Altitude exerted a favorable influence, owing to diminished humidity, higher diathermance, and its increased corpuscular count. The jolting movement sometimes had exerted gratifying results. The average modern city provided a favorable environment for some asthmatics. The vast majority of all asthmatics could be permanently cured in almost any locality favorable to animal life, under proper hygienic, dietetic and medicinal treatment, though the highest possible altitude, evenest temperature, most sunshine, and best drainage furnished the most favorable surroundings.

An Old Specialty.—Dr. Jane Lincoln Greeley of Jamestown read this paper. She pleaded for the old family doctor in maintaining the physical welfare of his clientele. Others may render more conspicuous service, but the family physician stands nearest to the daily life of the people. He gives of the stores that have accumulated. Other men concentrate their powers in the acquisition of special knowledge, but to the family doctor falls the dissemination of knowledge. The family practice had a definite field, and of work in this field no man need be ashamed. His work began with the beginning of the family. The family doctor was not primarily an obstetrician, although he had the medical supervision during pregnancy, and this implied more than the usual test for albumin. To him belonged the securing of proper nutrition, fresh air, nervous toning, which favored the development of an individual without physical handicap. The family physician was the guardian of the future. Any mismanagement during the first few days of life gave work to the pediatrist. The gynecologists state that much of their work arises from faulty conditions at birth. It is the family doctor to whom we must look for the prevention of such conditions by attention paid to inflammations of the genital tract. He not only treats acute disorders, but also the conditions so easily overlooked, which might result in a not too strong child. He should foresee disorders of the spine, throat, eye and ear, and even the teeth. The sanitary conditions of the house and vicinity are investigated by him, and he looks for possible dangers to the community at large as well. The family doctor is a public-spirited man, because the interests of the families are the interests of the community. No other man dealt so much with the beginning of things. The successful carrying on of such a practice involved certain preparations and a certain expenditure. He should have a good general education and he should be familiar with other things besides medicine; he should be interested in education, in labor, and in diversions. He really needed the equipment and discipline required of medical men to-day in taking up technical studies. He should be especially well read. His work called for the study of human nature, but an absolute requirement was character.

An Atypical Case of Appendicitis Presenting Some Unusual Features, Found at Operation.—Dr. W. B. Reid of Rome reported the history of a patient, forty-nine years old, whose general health had always been good with the exception of chronic indigestion, associated with pains in the side. After walking or standing for some time the ankles would swell. On February 17 the patient was thrown from a sleigh and, that night, pain developed in the hypochondriac region. On the morning of the second day the pain was in the left lumbar and iliac region. The abdomen became sore and tender. When examined by the doctor the patient had an umbilical hernia, associated with a general tympanites. There was marked tenderness over McBurney's point, and a board-like rigidity. Pulse was

110, temperature 101°, respirations 24. The bowels had not moved for three days. Examination of urine revealed a large number of pus cells and granular and hyaline casts. The diagnosis of a traumatic appendicitis was made. Because of the condition of fatty heart and bad kidneys, operation was deferred. Operation under cocaine anæsthesia was not thought of. On March 11, he again saw the patient, who was much worse. The abdomen was generally tender, with some localized pain in the right side. A tumor was noted about the size of an apple. The previous diagnosis was confirmed. Operation was performed, and a pus cavity was found with a gangrenous appendix sticking up. The interesting features of the case were as follows: 1. The case was one of appendicitis of long standing, as shown by the history of pain in the side and chronic indigestion. 2. The history of traumatism was purely coincident. 3. The acute attack was followed by the invasion of the colon bacillus and abscess formation. 4. The acute nephritis was caused by an infectious toxæmia, as the post-operative examination proved the urine to be free from albumin and casts. 5. The associated diabetic condition furnished a sufficient amount of sugar in the culture media contained in the abscess cavity for the production of gas formation. He asked if they had a double infection of the bacillus coli communis and the bacillus lactis aerogenes, or was the infection a single one of the bacillus coli communis, which under peculiar conditions produced what was ordinarily called "involution forms," which resulted in gas formation.

Nephroptosis, Its Gynecological Importance.—Dr. A. H. Goelet of New York read this paper (see page 641).

The Value of Transillumination of the Stomach as an Aid to Diagnosis. A New Method with Fluorescent Media.—Dr. Robert Coleman Kemp of New York presented this communication. He referred to the nature of the substance used and his method of using it. When fluorescin had been given by the mouth no deleterious effects had resulted, as shown by an examination of the urine. Dr. Valentine had used this substance to test the permeability of the kidneys, and with good results. Transillumination of the stomach was an aid in investigation of mucous colic. Gastroptosis was one of the chief etiological factors in mucous colic. Mucous colic was present in many cases of Glénard's disease. It was an established fact that neurasthenia was an accompaniment of all cases of mucous colic. Dr. Kemp had been able to demonstrate gastroptosis as an etiological factor in this condition, which was due to abnormal positions and not to inflammations. Transillumination was of aid in differentiating between dilatation of the stomach and gastroptosis; it also told of the degree of dilatation and prognosis. Dr. Kemp demonstrated the use of the abdominal belt of Dr. Rose, which was of such great importance in the treatment of gastroptosis and dilatation of the stomach. The standard width of this strap was seven inches, and it could be worn for weeks. It should not come higher than the umbilicus, and was best applied with the patient in the Trendelenburg position. The value of transillumination was in exploration of the anterior wall and the greater curvature of the stomach of tumors, and of thickenings, and of explorations at or beneath the dostal arch. It was also of value in differentiating carcinoma or other tumors in various parts of the gastro-intestinal tract. By its means one was able to differentiate gall bladder disease from dilatation of the stomach, and determine the positions of contractions and of adhesions. Dr. Kemp said that there was no other method which could take the place of transillumination, especially in making a diagnosis of tumors at the pylorus or anterior wall of the stomach. When the light was introduced, one could not only see the entire contour of the greater curvature, but also the lateral margins of the stomach and the pyloric end. In cases of gastroptosis, where the stomach was vertical, one might be led astray. In such cases, when you inflate this organ with air, you might also force some intestines over the lesser curvature.

A Substitute for Rubber Gloves in Surgery.—Dr. Frederick Holme Wiggin of New York said there were a great many annoying features in connection with the use of rubber gloves in operative work. Attention was called to a substitute which had given him the greatest satisfaction. In the hospital the following was prepared: 49½ ounces alcohol (96 per cent.), 49½ ounces of ether, ½ ounce of celloidine and 1 ounce of castor oil. The hands of the operator were sterilized and then dipped in this solution. This gave a thick, firm, dry, elastic coating that did not crack and which was not soluble in water or ordinary alcohol. It could be removed by washing in equal parts of alcohol and ether.

Salivary Calculi.—Dr. Herman Jarecky of New York reported three such cases. The first calculus was situated in Wharton's duct, and at the same time one was situated in Blandin's gland. Only two such cases were found in a search of medical literature. The one in Wharton's duct weighed four grains, the one in Blandin's gland one-half a grain. In the other two cases reported, the stones were found in the submaxillary ducts. The fact that two calculi could occur in two different glands formed the basis of his paper.

Dr. Wolff Freudenthal of New York said that it was quite remarkable how many people could stand the presence of large calculi in these ducts for many years without noticing them. He did not believe that these calculi were as rare as generally believed.

Dr. G. Lenox Curtis of New York said he had operated upon at least twenty cases similar to the ones reported, and did not consider the condition at all rare.

Ten Years' Experience with a Radical Operation for Carcinoma of the Breast.—Dr. Willy Meyer outlined the technique of this operation, which has already been reported. In this operation no ligatures were applied until its completion, drainage was instituted, blood vessels ligated, and immediate grafting was done and dressings applied. The average time of operation was about two hours. The surgeon works from the axilla downwards to enable him to secure the vessels near the trunk; the procedure is quite bloodless and recovery is rapid. In ten years' experience with this operation he had only once been called upon to give intravenous injections during operations; in no other case was hypodermoclysis required. Eighty cases had been operated upon, and only two of these had died from conditions connected with the operation. One of these was a diabetic, and the other had recurrence of the carcinoma. The total removal of the pectoralis major muscle did not take away the free movement of the arm. With regard to statistics, he was unable to present any accurate data as yet regarding the duration of cure, or recurrences, local or general, because, in large cities, it was almost impossible to keep track of your patients. He hoped to present definite and full statistics regarding these cases at some future date.

Prolonged Fasting as a Factor in the Treatment of Acute Diseases, with Special Reference to Affections of the Alimentary Canal.—Dr. Norton Jerome Sands of Port Chester read this paper. He summarized by stating that in acute illnesses in general, but especially of the alimentary canal, when of great severity, food should not be given, because the assimilative powers of the patients were greatly impaired. In affections of the alimentary canal, in particular, all nourishment should be withheld until the tongue was clean, the bowels regular and the temperature normal. He said that it was quite possible for patients to fast three or four weeks without the development of any pronounced weakness.

Dr. Frederick H. Wiggin of New York said that, in surgical sepsis, he relied upon castor oil and glycerin by the mouth, and the giving of saline solution by the bowels, two or three quarts a day. As the temperature receded, he gave plenty of water by the mouth, and finally resumed feeding by the mouth.

Resolution.—Dr. Bernard Cohen of Buffalo said that the unfortunate delay in the amalgamation of the New York State Medical Association and the Medical Society of the State of New York was not due to any fault of either body, and was a source of disappointment to the Association, and he offered a resolution to the effect that it was the unqualified desire of medical men that good fellowship should prevail and that the Association pledge itself to aid in securing a union of the two organizations.

Concerning the Suppression of the Acetone Bodies in Diabetics.—Dr. Heinrich Stern presented this communication, and said, in diabetes, the acetone substances always indicated a state of under-nutrition. This may be due to a too long continued one-sided diet, but it might also supervene when sufficient proteids and moderate quantities of carbohydrate substances are contained in the diet. He further stated that the production of acetone substances would not occur as long as one can manage the diabetic to be in a fair state of nutrition. Von Norden's "oat-meal cure," he thought, was not commensurate with the rationale of acidosis therapy, as the large amounts of butter which entered into the composition of the oat-meal soup certainly would yield a very considerable additional quantity of acotone substances. Furthermore, the patients soon became tired of the monotonous regimen, and it did not uphold the claims of its author. Oatmeal was not better tolerated by the diabetic exhibiting acetonuria than other amyloid substances, as buckwheat or rice. If we wish to successfully combat acidosis without aggravating the diabetic condition, we can neither add carbohydrates to the diet for any length of time, nor can we, in most cases, augment the amount of proteid ingesta. There was nothing left but to return to fatty substances, that is, to such fatty material which did not yield the forerunners of the acetone bodies, viz., the low fatty acids. Butter and cream yielded very large amounts of these low fatty acids. The only fatty article of food which he found of good use in the diabetic during acidosis was the yolk of the hen's egg. He had never observed an increase of acetone after the administration of what he called the "yolk cure." Partaken of in the raw or semi-raw states, fresh yolks might be consumed in almost any quantity without calling forth satiation or fullness. The rationale of the "yolk cure" he based on the following four factors: (1) Palmitin, stearin, olein, the fat substances of yolk yielded no or little butyric acid; (2) the large amount of lecithin supplied to the organism, restored the nerve force and ameliorated the wasting condition; (3) the occurrence in the yolk of a diastatic ferment aided in starch-conversion; (4) the stimulating action of yolks on the gastric secretion. The yolk-cure consisted in the ingestion of from ten to forty yolks a day, together with a small amount of proteids and some carbohydrates. Its technique was simple. The old diet was to be discontinued at once. Intestinal tract should be evacuated. In grave cases, a yolk-diet had to be continued for some time, in less severe cases, one or two "yolk-days" a week, together with proteid-fat (yolk) days, sufficed. The alkalies exert a mere local and limited influence. They may be administered together with the "yolk-cure," but they had no influence whatsoever on the catabolic acidosis. He gave a "yolk menu" full of variety. He also appended a number of cooking receipts for "yolk-dishes." He presented a boy, sixteen years old, who came to him in March last, weighing 98½ pounds, and excreted almost 400 grammes of sugar a day. His urine contained very large amounts of acetone and diacetic acid. After everything had failed, he tried his "yolk-cure," with the result that the sugar excretion had entirely ceased and that he did not produce acetone or diacetic acid for a number of months. His weight in October 15 amounted to 122½ pounds.

The Brief Story of a Smallpox Epidemic.—Dr. Edward Munson of Medina gave a brief history of this epidemic, which presented the following points of interest: The epidemic was undoubtedly smallpox; it was variola, uniformly of mild variety; the vesicles were unilocular; secondary fever occurred only in two or three cases; the exceptionally mild character of the disease made it almost impossible to properly quarantine; the value of vaccination in stamping out the disease was demonstrated.

Some Ocular Reflexes and Their Influence on General Health.—Dr. S. W. S. Toms of Nyack read this paper. He had examined one thousand eyes as part of his routine work, and had been convinced that many patients would have gone on unrelieved had such examinations not been made. His paper did not relate to patients with organic diseases which gave eye symptoms. Slight visual defects might produce profound disturbances. Hysterical emotions may be produced by uncorrected eye troubles. Astigmatism was very productive of reflexes. Muscular unbalancing was potent. The more frequent and common symptoms of ocular reflexes were the different types of headache, vertigo, nausea, vomiting, nervous disturbances, cardiac neuroses, nervous spells, etc. A report of cases followed.

THIRD DAY, OCTOBER 19, 1904.

Report of Twenty-Five Cases of Pernicious Anæmia.—Dr. A. E. Woehnert of Buffalo reported 25 cases of pernicious anæmia from the standpoint of the hæmatologist. The clinical features of these cases had already been considered by Dr. Charles G. Stockton of Buffalo at the June meeting of the American Medical Association. Not only was the diagnostic importance of the blood taken up, but also the prognostic. In these cases, when the blood was withdrawn from the finger, it was found to be less viscid and darker than normal. When the blood was much impoverished it looked more like water than blood. The microscopical examination showed differences in size of the cells, especially of the red cells; they were increased in diameter and this was a marked feature. Of the cases reported it was found that the number of erythrocytes varied from 628,000 to 2,440,000 to the c.m. The leucocytes varied from 2,400 to 12,344. The differential count of the white cells showed an average of polymorphonuclears 61 per cent., of lymphocytes 33 per cent., large mononuclears 4 per cent. and eosinophiles 2 per cent. The specific gravity of the blood taken in 11 cases was from 1,037 to 1,051. The hæmoglobin ranged from 23 per cent. to 65 per cent. Pernicious anæmia was characterized by a high hæmoglobin index, the average being 122 per cent. The increased size of the red cells accounted for this in part. Macrocystotis was the rule in all cases. Another feature noted was the irregular contour of surface of the cells, many of the cells losing their bi-concavity. In some cells the nucleus took a stain and was separated from the rest of the cell by a light zone. In summing up the findings he stated that pernicious anæmia was a symptom complex showing itself by characteristic disturbances in the blood, and that it was the action of toxic material that caused these disturbances. This toxæmia showed itself by a granular degeneration of the cells. The blood destruction showed itself by the peculiar tint of the skin and the increase of iron in the internal organs.

Dr. J. J. Walsh of New York said that many of the rarer diseases, of which pernicious anæmia was one of the most pronounced, were now found to be much more frequent than was formerly thought. For instance in diabetes there was a curious discrepancy regarding it. Formerly it was thought that only one half as great a number of these cases existed in America as in Europe, but the statistics to-day showed comparatively the same number here as in Europe. In other words, the disease was being discovered, and the same seemed to be true regarding pernicious anæmia. The question of etiology was an interesting problem that confronted us. He referred to what a distinguished English physician claimed to have found that pernicious anæmia was often due to bad teeth; that in the presence of carious teeth cocci were swallowed and septic conditions set up in the digestive tract, etc. Since that time Dr. Walsh had examined the teeth in five cases, but in two the patients had the best teeth he had ever seen. Hunter

had suggested the use of the antistreptococcic serum in pernicious aæmia, but Dr. Walsh had been disappointed in its use. He had tried this serum in one case with clean teeth for a period of eight weeks; by the tenth week the patient was dead. In Europe many people still believed in Hunter's theory.

Dr. B. W. Stearns of Binghampton spoke of the structure of the blood being similar to the structure of other tissues. As the red cells increased the leucocytes decreased, as shown in the paper. In malignant growths it was noted that the malignant cells took the place of the normal cells. In the same way in pernicious anæmia the abnormal cells might take the place of the normal.

Dr. Woehnert said that the teeth in all cases had been most carefully examined, and he had noted that the worst cases in the list he presented had the best teeth. Dr. Stearns evidently had misunderstood him, for the point he made was that in the majority of cases as the red cells decrease the white cells decrease also.

Some Occupations and So-called Rheumatic Pains.—Dr. James J. Walsh of New York read this paper and stated that in dispensary and office work nothing was more frequent than to have patients complain of pains, especially on rainy days, which they believed to be rheumatic. Chronic rheumatism was supposed to be one of the most frequent diseases, and the explanation has been made that the circulation was too passive. As a consequence, there was nervous irritability and the blood was not nutritious. During the past five years there had occurred a decided reaction regarding the so-called uric acid diathesis; at the present time very few scientific men considered uric acid of any etiological importance in the production of pathological conditions of the body, except possibly gout. In all these cases, when the causation had been determined, treatment was made easy. In many of the so-called rheumatic patients pains in the shoulder were not infrequent. He had three such cases in one day, one being a motorman. The second man had an occupation in which he used the deltoid muscle, using a hammer. The third man complained of pain in the left hand and forearm, especially on the ulnar side; he constantly used the muscles supplied by this nerve. In all these three cases in all probability a neuritis had been set up for which he could not give a satisfactory reason. It was possible that the ingestion of alcohol might prove the cause. Lumbago was quite common among tailors, as well as among iron workers and molders. So-called rheumatic pains were noted among those who suffered from lead, alcohol, diabetic, syphilitic, etc., poisons which exercise an influence upon the nerves. Sciatica was quite common in those who bent the body at the hips, as in shovelers. Motormen, who were accustomed to stand on one foot, suffered from lumbago. Also dentists in using the old engines were found to limp. Those occupations which caused people to stand upon the foot would have pain referred to the same leg, which would be worse on rainy days. These pains that were worse on rainy days were probably due to the wearing of old shoes, which failed to give the foot proper support. Dampness and rheumatism seemed to be associated in all minds. Sciatica was often found in those who sat in awkward positions.

Dr. William M. Bemis of Jamestown had had a similar experience, and had been puzzled a great deal regarding these so-called rheumatic pains. He had had a great many cases of cramps in the legs and feet and had been at a loss to know how to account for them. He finally found that supporting the instep would relieve these cramps. He had seen cases of general neurasthenia due to pain in the back, and the probabilities were that some pressure upon the nerve low down at the sacro-iliac junction had been present, and this was relieved by support and holding up the upper portion of the body, thus relieving pressure upon the tender nerves.

The Alexander Operation. Its Results, Immediate and Remote.—Dr. James E. King of Buffalo considered a few of the clinical features resulting from operation. This operation had been much criticised, but the results of the operation had placed it upon a firm basis. Successful results were only possible when the indications for it had been carefully considered. It should never be undertaken unless its complications, such as of the uterus and adnexa, were treated at the same time. The indications for this operation were simple, uncomplicated retroversion, and this implied a very careful diagnosis. In dealing with retroversions, one should remember that the condition was not pathological, but mechanical. Where relapses occurred, they were due to suppurations or small ligaments, and failures should not be charged to the operation. When relapses did occur, they were from the patient's view, rather than from lack of mechanical support. One of the most unpleasant sequella was pain, usually unilateral, extending up about three inches on the abdominal wall. Any pressure brought it on. They often remained for four or five months with gradual improvement, until they finally disappeared. When very severe, the patients were unable to wear corsets. The cause of this pain seemed to be injury to the ilio-inguinal nerve. This nerve, as it passed through the inguinal canal to its cutaneous distribution, had an anatomical relation to the round ligament. Great care should be observed in avoiding handling this nerve, and it should not be sewn in with the fascia. As a rule, little could be done for its relief. Another result of the operation sometimes seen was the failure to correct the retroversion and relieve all symptoms. In some cases of retroversion the symptoms seemed to be due to the condition of the utero-sacral ligaments; in two cases that he reported the symptoms were due to a relaxation of these ligaments, and prompt relief was afforded by operation. Hernia following operation was usually due to faulty technique or suppuration. He stated that the operation was admitted to have no influence on pregnancy or labor, and no recurrences had followed labor.

Dr. Henry O. Marcy of Boston said that when the operation came into vogue he was very enthusiastic about it, and he did many operations with varying results. That he had now ceased to do the operation might be considered an adverse verdict. However, opening the abdomen now was attended by comparatively little danger, and he preferred so doing because it enabled him to deal with the conditions as found. He believed there was a limited field for the operation, but far less than he had at first thought.

Dr. J. Riddle Goffe of New York had had the same experience with the Alexander operation as had had Dr. Marcy. He found it sometimes impossible to locate the ligament and sometimes, when he did find it, it was not sufficiently strong to do the work required of it. He had, therefore, discontinued doing the Alexander operation. The field for this operation was very limited. He had followed up all cases that he had submitted to operative procedure for retroversion of the uterus, and had found that 80 per cent. were complicated by disease of the appendages, that reduced the operation to only 20 per cent. of all cases of retroversion, and this was an extremely limited field. In regard to using the round ligaments for supporting the uterus, he believed they were not designed for this purpose. He had reduced his observation to the following: When the bladder filled, especially to extreme degree, the fundus was raised to the promontory of the sacrum. When the bladder was emptied, the round ligaments drew the fundus back to an anteverted position. Consequently, he believed the function of the round ligaments to be, during gestation, to keep the fundus against the anterior abdominal wall. In cases of tumors or pregnancy, when the intestines got in front of the fundus, they may become strangulated. The proper supports of the uterus lay in the utero-sacral ligament. If they retained their tone they would keep the cervix in the hollow of the sacrum and prevent retroversion. In case of procidentia, he shortened these ligaments with the most satisfactory result. He said that Nature's plan was to support all organs of the body from the bony framework by ligaments; there was no other organ of the

body that had so many ligaments as the uterus; notwithstanding, some stated that it was supported by the perineum. As a matter of fact, when the perineum was ruptured absolutely, no possible support could be obtained from it, yet the uterus remained in place. The ligaments were the proper structures to use for supporting the uterus.

Dr. James E. King of Buffalo said that he did not intend to advocate the Alexander operation to the exclusion of other methods for the treatment of retroversion. He believed it had its place. One argument in favor of its performance was that many refused abdominal section. He wished to emphasize the fact that the Alexander operation was only indicated in persons without complicating diseases of the uterus or adnexa, and a careful diagnosis implied many examinations and a study of the symptoms accompanying the condition.

Iodine in the Treatment of Post-Operative Sepsis.—Dr. James Hawley Burtenshaw of New York said that this treatment was first proposed in 1883 and to Dr. William R. Pryor of New York belonged the credit of placing this method of treatment on a scientific basis. Dr. Pryor published his paper on this subject in the *New York Medical Journal*, January 23, 1904, when he reported 27 cases. Iodine had a pronounced affinity for protoplasm as had been demonstrated many times. In the majority of cases the infection spread from the uterus through the lymphatics. In post-operative sepsis the blood vessels played as important a rôle as the lymphatics in the dissemination of the toxins. Dr. Pryor showed that if the pelvis was packed with iodoform gauze the absorption of iodine was rapid, the growth of the germs was inhibited and the course of the infection greatly shortened. Dr. Burtenshaw's experience with iodine in such cases had been disappointing. During the past year he had treated three cases of post-operative sepsis with two fatal results. It had been claimed that iodoform was not an antiseptic for all bacteria, but it was also well known that when broken up iodine was liberated. He referred to the use of equal parts of iodoform and cod liver oil in the treatment of tubercular peritonitis; when this was applied to the skin of the abdomen every day good results had been obtained.

President's Address.—Dr. William Harvey Thornton of Buffalo took as his subject "Medical Fellowship." He said that the best men in the profession were those who were active in medical societies and they appreciated the value of cooperation and organization. In medical organization many failed to appreciate active membership in a live working body. As citizens they appreciated local, state, and national government, but they failed to apply the same principles to themselves as physicians in national and state organizations. He spoke of the importance of maintaining the honor of the noble profession, and this did not rest upon contention and jealousy. Fellowship begets friendship and destroys petty jealousy. The first step in harmonizing the profession was membership in some society. He said that much had been done in this state by the state officers visiting the various county and district societies. The county association should be made interesting scientifically. Good papers should be obtained and good leaders should be had to open discussions. The social features added greatly to the interest and promoted a feeling of harmony which was so much desired. The point that he wished to emphasize which was of vital importance to any society was to reach and interest and hold every man within its jurisdiction, and to make him an active worker. Out of 1,800 members in this society he was glad to report that 1,000 were members of the American Medical Association. The national charter would secure to this organization much power and usefulness. There was a demand for unity of the profession in the State of New York, and nothing could stop such a want. He asked for continuous efforts to make the Association nearer the ideal that they had striven to attain.

How and When to Use Antitoxin in Diphtheria.—Dr. Charles Gilmer Kerley of New York read this paper. He desired to call attention to certain points pertaining to the use of antitoxin. Diphtheria antitoxin should be used in every case of acute illness in which a pseudomembrane appeared in the throat or nose. Even when in doubt whether the exudate is diphtheritic or not give antitoxin and then take a culture; do not wait for the culture diagnosis before giving antitoxin. The earlier the antitoxin is given the less amount will be required. He had treated 66 cases of diphtheria in private practice with antitoxin. The ages ranged from nine months to ten years. Sixteen of the cases had been intubated; 14 received the antitoxin on the first day of illness; in 13 only one injection was necessary. In one it was only necessary to repeat the serum on the second day of illness. There were twenty-four non-operative second-day cases; in 19 only one injection was required; in 4 it was necessary to repeat the injection on the third day; one received four injections, getting a total of 14,500 units. One case that he saw on the sixth day required five injections or 14,000 units to control the disease. He emphasized the fact that antitoxin should be given in laryngeal persistent stenosis. Again in those cases which did not respond to emesis it should be given at once. Especially should it be given where there was obstruction to inspiration and expiration. Of the laryngeal operative cases, 16 in number, 13 recovered and 3 died, the latter receiving the antitoxin too late. The antitoxin should be given in immunizing doses to every child exposed. Patients seen on the second day of disease should receive 3,000 units regardless of the age; after the third day 5,000 units should be given as the initial dose, to be repeated in twelve hours if the improvement was not positive. The abdomen was selected as the point of injection. Twenty per cent. of the patients developed urticaria. In 5 cases that did not have diphtheria no bad results followed the injection. Nephritis did not develop in any of the cases. In 4 there was a diphtheritic paralysis of mild degree. He said that in diphtheria we were dealing with a poison, and the antitoxin was a specific antidote. He said that we should make the dose fit the case, and the dosage was determined by the severity of the infection when first seen.

Dr. Everard D. Ferguson of Troy said that before the introduction of antitoxin he had had seventy-five intubations without a single recovery. Immediately after the introduction of antitoxin he treated successfully five cases of primary laryngeal diphtheria.

Dr. Louis Curtis Ager of Brooklyn did not think the dose of antitoxin diphtheria should ever be less than 3,000 units.

Dr. Francis J. Quinlan of New York said that since the introduction of antitoxin the danger from diphtheria had been reduced almost to a minimum. Before the antitoxin was discovered, in one year he did one hundred and sixteen intubations; shortly after that the general use of antitoxin took its place. The timely use of antitoxin eliminated all bad symptoms, especially in the laryngeal and tracheal form of the disease.

Dr. Bernard Cohen of Buffalo had given 28,000 units in two days. This large dosage was called for because of distressing symptoms, especially the cardiac weakness.

Dr. Louis Fischer of New York said that in severe cases of diphtheria he did not think that we should ever give less than 5,000 to 10,000 units as the initial dose. He had given 20,000 units to a child in four days. In laryngeal cases the initial dose should be 10,000 units. He said that we should not rely upon antitoxin only. When antitoxin was thrown into the system it neutralized the toxins, and so arrested the development of complications which might arise.

The Result of 1,400 Operations for the Radical Cure of Hernia in Children, Performed at the Hospital for the Ruptured, and Crippled, from 1891 to 1904.—This paper, by Dr. William T. Bull and Dr. William B. Coley of New York, was read by the latter. From 1890 to 1903, 49,974 patients were treated for inguinal and femoral hernias, and more than one-third, 14,218, occurred in chil-

dren under fourteen years of age. Operation was seldom advised in cases under four. The results of operation were quite uniform, and the mortality was practically eliminated, and, therefore, operation was advised in children over four years of age. It was important to know the proportion of cases that were curable by truss treatment. This was very difficult to tell. Of 709 cases carefully examined, it was shown that the sac was congenital in 284 cases, and of the acquired type, 425. There were twenty-seven cases of femoral hernia under the age of fourteen. Since 1890, 2,179 cases of femoral hernia had been observed, sixty-nine being under fourteen years of age, and thirteen of these under ten years. High ligation of the hernial sac was performed without a single relapse. There were 229 operations for inguinal hernia on 222 patients. The operation performed was practically a Bassini. The veins of the cord were not excised; this he considered unnecessary in children. The purse-string method was used in femoral hernias. In 108 operations, the cord was not transplanted, but brought out at the lower end of the wound. The Bassini method, without transplantation of the cord, had been strongly recommended. Thirteen cases of hernia of the cæcum and appendix were reported. When the normal appendix was adherent to a hernial sac, it was thought best to remove it. There were two cases of sigmoid hernia, which was very rare in children. There were twelve cases of strangulation in children under fourteen years of age. The strangulation, in all cases, was the result of tight constriction at the external ring.

Dr. Henry O. Marcy of Boston referred to his first operations with buried suture for the cure of hernia, which were published by him in 1870.

Dr. Frederick H. Wiggin of New York strongly advocated the use of kangaroo tendon as sutures in adbominal wounds.

Dr. William B. De Garmo of New York only operated upon those who were over four years of age. He had operated 228 times on 182 children, without any relapses, and with but one death, and this from acute syphilitic meningitis. He said that congenital hernia could be cured by truss, but that it was more difficult than in the acquired form.

Dr. William B. Coley of New York said that there were many cases of congenital hernia that could be cured by means of the truss, and that it was impossible to say whether the hernia was congenital or acquired until we had operated.

A Group of Cases of Tumor of the Orbit, with Conclusions as to the Treatment of Such Cases.—Dr. Charles Stedman Bull of New York presented this paper, which was read by title.

Infant Mortality in New York City.—Dr. Louis Curtis Ager of Brooklyn presented this, mainly a statistical paper. He stated that in New York, since 1898, there had practically been no improvement in infant mortality. Diarrhœal diseases in children under five years of age for seventeen summer weeks showed the following number of deaths: In 1902, 3,201; in 1903, 2,735; in 1904, 3,810. The number of deaths from diarrhœal diseases in children under five years of age per 100,000 of total population for the year 1898 were 224 for Brooklyn, and 191 for Manhattan; in 1899, 180 for Brooklyn, 102 for Manhattan; in 1900, 196 for Brooklyn, 160 for Manhattan; in 1901, 194 for Brooklyn, 161 for Manhattan. The death rate per 100,000 of population of diarrhœal diseases of all ages showed for New York County, 170; for Kings County, 200; for Queens County, 216, and for Richmond County, 228. The population of Brooklyn in 1902 was 1,166,582; of Manhattan, 1,850,093. The population under five years of age showed 28,961 for Brooklyn, and 46,796 for Manhattan. The percentage under five years of age was 2.48 for Brooklyn and 2.53 for Manhattan. The ratio showing the use of condensed milk and fresh milk for Manhattan was 1.4; for Brooklyn, 3.1. The amount of fat, casein, milk and cane sugar were shown by percentages in condensed milk mixtures and human milk.

Dr. Louis Fischer of New York said that the high or low mortality depended upon the absence or presence of breast milk. There was very little summer complaint among children of the breast-fed. The importance of cleanliness and proper education of the mother was emphasized.

Dr. Charles G. Kerley of New York said that the education of the mother was the solution of the problem of the tremendous mortality among children.

Prostatectomy in Emergency Cases.—Dr. John F. Erdmann of New York called attention to the advantages of doing this operation in every instance possible when the prostate was in part the cause of obstruction in cases coming under the head of emergency drainage of the bladder. The first case was one of impassable urethra, due to stricture, with rupture and gangrene of the entire scrotum and perineum. The second case was one of retrograde hemorrhage, the bladder being full of clots and bloody urine, with malignancy of the prostate. The third case was one in which there were false passages, retrograde hemorrhage and suprapubic aspiration, with infiltration of the abdominal wall extending to the thorax and to the gluteal regions. The fourth case was one of acute obstruction, due to exposure to cold and wet, with inability to catheterize, and trauma of the urethra. The fifth was one of trauma of the urethra, in which catheterization had been performed for three days, with retrograde hemorrhage and large prostatic obstruction. The sixth case was one of deep stricture of the urethra, with obstruction and cystitis with absorption. The seventh and eighth cases were obstructions, with slight trauma, to the urethra, in which it was advisable to operate, both because of trauma and for drainage. This emergency operative procedure was recommended, because only a few minutes more were required to remove the gland, and the hemorrhage, as a rule, was not excessive, and the operative procedure itself did not increase the shock to any degree. The removal of the prostate gave proper exit to the urinary outflow and admitted of easy drainage. Washing the bladder was much facilitated. The perineal route in emergency operations was recommended, because the opening was practically at the lowest point of the bladder, and complicated devises for drainage, such as were required in suprapubic sections, were not necessary. The old, being irritable and feeble, and requiring to be moved frequently, the drainage in the suprapubic method was constantly interfered with, while in the perineal method it was readily controlled. The after-soiling, when the tube was removed, was slight and easily controlled, in the perineal method, as compared with the suprapubic. The bladder irrigations were more readily done, with less soiling of the bed, by this method.

Clinical Observations in Scarlet Fever with Special Reference to the Heart and Other Complications.—Dr. Louis Fischer of New York said that in this disease more attention should be paid to the heart and less to the temperature. Some important questions arose for consideration, as follows: (1) Was the temperature a positive indication of the condition of the patient? A moderate rise of temperature was often encountered in the most malignant forms of the disease, and, on the other hand, the mildest forms of scarlet fever sometimes begin with a temperature of 102° to 105° F. Therefore, one could not say that very high fever was any guide to the severity of a given case. (2) Does fever invariably indicate disease? No. This was a fact that he had frequently verified. He had operated on cases of empyema in which there had been a normal temperature for days, and he had seen other suppurative complications without any fever. He was convinced that too much stress was laid on the fever, and the temperature curve was given far more credit during convalescence than it deserved. (3) Was the decline of temperature always a favorable sign? A drop of several degrees in the temperature did not indicate improvement in all cases. Frequently a complication will be detected

when the temperature indicated improvement. He believed the toxins of scarlet fever inhibited the proper action of the thermic center in the brain, because the most malignant form of this disease frequently showed no rise, or only a slight rise above the normal. (4) By which symptom should we be guided in determining a favorable or unfavorable termination? The greatest attention should be bestowed on the condition of the heart. The pulse, its character, its frequency, and its tension were the most important guides. The necessity for immediate support of the system was apparent if the heart and pulse rate were studied. Experience had taught him that he was facing a danger point when feeble or muffled heart-sounds were noted or a bruit was heard, when, during this same time, a normal temperature would have been a misleading factor. The mortality in private practice was high, and he accounted for it simply by the one fact, that children were not kept in bed long enough to permit the toxæmia to be modified. Every case of scarlet fever was kept in bed at least four weeks. The temperature of the room should be between 68° and 70°, and ventilated frequently. The temperature was no guide as to the time when the child should be permitted out of bed. The heart and the pulse should be the true determining guide as to the prognosis and the condition of the patient. The diet should be liquid, principally of milk and alkaline waters. The emunctories should be stimulated. A hot saline colon flushing, one or two quarts, at a temperature of 115° to 120° F. should be given once a day after the first week, regardless of the necessity of the same. It stimulated diuresis, cleansed the bowel, and nourished the blood.

THE SEVENTY-SIXTH CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

Held at Breslau, September 18-24, 1904.

(Continued from Page 636.)

The Colorless Cells of the Blood and Their Clinical Significance.—Dr. Grawitz of Charlottenburg read a paper on this subject. At present three varieties of cells are distinguished: the small mononuclear cells, the polynuclear neutrophiles, and the easinophiles. Although Ehrlich attaches much importance to the minute differentiation of the cells, Arnold as well as others, points out that the staining methods are not always reliable and that in a single cell, for example, differently stained granules may be found. It must also be remembered that the various forms of leucocytes indicate only different stages of development. It therefore follows that laying stress on the different types is out of place and that progress in this direction is not likely. For not only do defensive and phagocytic (Metchnikoff) properties come into play but also assimilating, and as has been proved for fat, iron, and albumin, absorbing functions. In addition there must be ascribed to them an ozonizing and fermentative coagulating activity. Clinically there are observed increased and diminished numbers of leucocytes, changes in their relative proportions, and pathological forms. Hyperleucocytosis occurs after meals, during labor, accompanying the action of heat, cold, etc., and in suppurative processes. High leucocyte counts indicate a favorable prognosis in appendicitis and peritonitis. Typhoid fever shows hypoleucocytosis, pneumonia a hyperleucocytosis. In carcinoma the conditions are uncertain, and in leukæmia atypical forms occur.

Origin and Destiny of the White Blood Cells.—Dr. Askanazy of Königsberg said that concerning an understanding of their origin there were, among others, two difficulties, the defectiveness of our knowledge of their development and the uncertainty of the question whether the leucocytes are or are not an organ by themselves. In the embryo the liver, spleen, lymph glands, bone marrow, and thymus produce leucocytes. In extrauterine life the bone marrow is most actively concerned in blood formation, and then come the lymph glands, while the spleen comes in question but little or not at all. The speaker had found that the red marrow of the ossified laryngeal cartilages produces leucocytes. The formation of granular cells takes place only in the bone marrow, and they are descendants of non-granular forms. Leucocytosis depends on chemotaxis and not on a simple passive washing out of leucocytes, for in this case all constituents would be washed out also. Neumann's old theory of leukæmia, ascribing a myelogenous origin to every case, is opposed to Ehrlich's view to the effect that myelogenous and lymphatic cases must be strictly differentiated. The speaker agreed with Neumann. The leucocytes are phagocytes and, in contrast to other stationary tissue cells possessing this property, are wandering phagocytes. Metchnikoff's view that leucocytes can heal disease through phagocytosis of bacteria is not tenable, but on the other hand these cells take part in the production of defensive bodies in the blood. Outside of the blood stream the leucocytes purify the inhaled air by taking up dust in the lungs, and are also active in the intestine in an as yet unexplained manner. Injured tissue is disposed of through the digestive powers of leucocytes, and the dead bodies of leucocytes themselves serve as building material for younger cells.

The Present Standpoint in Regard to the Eosinophile Cells.—Dr. Ehrlich of Frankfurt presented a communication with this title. He first defended the specificity of the eosinophiles against Arnold and other observers. Young eosinophile cells give different colors, and the neutrophiles, when heated, take up acid dyes. Eosinophiles occur in the bone marrow, but not in normal lymph glands. In myelogenous leukæmia, many easinophiles are found in the blood, but in lymphatic leukæmia there is only one per cent. of these cells. Furthermore, eosinophiles occur in asthmatic sputum and, as American observers particularly have shown, in trichinosis. They are of assistance in diagnosticating early cases of typhoid, and are found in some skin diseases. Eosinophiles have been found in great numbers in hemorrhagic exudates, and such fluids are very toxic for experiment animals. The injection of pilocarpine may change a pseudoleukæmia into a genuine one. Detailed differentiation of the various types of cells is very important.

Dr. Müller of Basle said that he agreed with Ehrlich's views regarding the differentiation of the leucocytes, although functional variations were also observed in leukæmia.

The Origin of Pulmonary Tuberculosis.—Dr. Aufrecht of Magdeburg showed some very interesting specimens, by means of which he endeavored to prove that pulmonary tuberculosis is of hematogenous origin. First the vessel wall is attacked, then a thrombus forms, and this becomes altered into a cheesy nodule.

Ultramicroscopic Objects.—Dr. Rählmann of Weimar demonstrated trachoma bacilli and leucocytes under the "ultramicroscope." In spite of the efforts of the observers, however, but few were able to adapt themselves sufficiently to the unaccustomed instrument to distinguish the various rods, spherules, and granules which were, according to the demonstrator, made visible only through their motions. It was only when a dead bacterium was carefully focused upon that they were able to make out its contours distinctly and to perceive that its length appeared twice as great as when viewed by ordinary methods. The interior of the leucocytes seemed to be made up of a confused mass of interwoven threads. As the speaker said, patience is necessary to acquire this new technique.

The Formation of Fat from Carbohydrates.—Dr. Rosenfeld of Breslau spoke on this subject. It is certain that fat can be formed from carbohydrates, but the question is, where? Organs such as the liver, muscle, and heart, which contain both fat and carbohydrates, never have shown an increase in the amount of fat after even forced sugar feeding. The same is true for the kidney, pancreas, and thyroid. As the fat originating in carbohydrates is deposited in the subcutaneous connective tissue, the blood flowing toward this region from an inner organ, the site of the transformation of sugar into fat, should contain an increased proportion of fat. As this is not the case, the fat must be pro-

duced in the place where it is deposited, i. e. in the cells of the subcutaneous connective tissue.

The Nature of Gout.—Dr. Falkenstein of Gross Lichtenfelde read this paper. Two factors are concerned in the disease, the defective secretion of hydrochloric acid by the gastric glands, and the diminished oxidizing power of the tissue cells. From these causes intermediate oxidation products arise which are most readily deposited in spots where the circulation is impeded. The other disorders of metabolism, diabetes and obesity, are to be explained on similar grounds. With these maladies it is not the disease which is hereditary, but the disposition to a metabolic irregularity. The interrelationship of these conditions is shown in that children of gouty parents develop diabetes or obesity instead of gout. Restriction of diet never cures disorders of metabolism, but a proper occupation is of great importance. Bodily exercise causing profuse perspiration is most essential, but must be instituted early; and in childhood migraine, constipation, and insomnia should be investigated. The speaker cited the case of the son of a gouty professional man, who remained free from gout by taking up agriculture, but whose son, again a professional man, became gouty. Women, on account of their housewifely activities, are less inclined to gout than men. The frequency of gout in England is due to the excess of nitrogenous food consumed, and the diminished perspiration caused by the damp climate. Through the aid of physiological investigations we are becoming better acquainted with the bodily forces, and in time even disorders of metabolism will be permanently cured.

Some Experiences with Hydrotherapy in Nervous Disorders.—Dr. Brieger of Berlin spoke on this subject, and stated that he was not in favor of the view that psychical treatment is the all-important thing in neurasthenia. Permanent results are to be achieved only by hydrotherapeutic procedures, carefully gauged by physiological laws and the powers of reaction. In neurasthenia, hysteria, migraine, and cardiac and sexual neuroses, he has had good results, and also in true psychical disorders, such as melancholia, mania, and beginning general paralysis. Hydrotherapy is also of great value in neuralgia, and though it is not a cure-all, should find more general application at the hands of the practitioner.

Tendon Operations in Infantile Paralysis.—Dr. Bade of Hanover read a paper in the Section of Surgery on this topic. He said that even though the cause of the deformity were central and incurable, still its results, such as club foot, and anomalies of position in the knee, elbow, and wrist joints, could be avoided. By lengthening, shortening, or transplanting certain muscles, the author had enabled children from eleven to nineteen years of age to acquire sufficient command over the hand to write, though this had previously been impossible.

Renal Calculi.—Dr. Löwenhardt of Breslau presented two patients. The first was a man whose kidney he had explored two years previously on account of unilateral renal pain, but as no stone was present he had only stripped off the capsule. The pain recurred and he then loosened the ureter as far down as the bladder. Although the kidney was hemorrhagic, twice the normal size, and nephritic, as was shown by ureteral catheterization, the patient has remained cured. The other patient had no tubercle bacilli in the urine, but on extirpating the kidney for the copious hemorrhages, it was found to be the seat of an ulcerating tuberculosis of the papillæ. In other cases the author has found tubercle bacilli in the urine, but no tubercles in the kidney, so that there was no reason for surgical intervention. The presence or absence of tubercle bacilli, by itself, is, therefore, not a safe criterion to follow.

Sciatic Hernia.—Dr. von Eiselberg of Vienna spoke of the unsatisfactoriness of operations for sciatic hernia. He had operated twice on a patient of this kind, and had finally been obliged to recommend a truss. He also presented a hair ball of the stomach which had extended into the duodenum and weighed 550 grams. The hysterical patient was operated on two years after first acquiring the habit of hair swallowing.

Gunshot Wounds.—Dr. Schmidt of Breslau discussed the infections following these wounds. The wads are responsible for most of the trouble, particularly those of paper, whereas those of felt are usually sterile. The paper wads are not subjected to any sterilizing process at any stage of manufacture, and of twenty guinea pigs infected with these, over one-half died of tetanus. The surgeon called to attend a gunshot wound should, if possible, at once examined the cartridge used, and if paper wads are found the wound should be incised and antitoxin injected. This would have good results, as the incubation period of tetanus is from five to ten days.

The Borderline of the Sexes.—In the Section of Anatomy and Physiology Dr. Magnus Hirschfeld of Charlottenburg read an interesting paper on this subject. In every organism, in addition to the characteristics of the one sex, those of the other are present to a variable degree, and the individual's mental and physical personality depends on the extent of this admixture. The author presented a case of mistaken sex in a woman who had masculine characteristics and internal sexual organs. Formerly, such people were styled hermaphrodites, but to-day it is recognized that they represent only extreme grades of sexual admixtures which exist in less pronounced form, both bodily and mentally, in great numbers of persons.

Chromatic Changes in the Iris.—Dr. Exner of Vienna described the modification of the color of the iris produced by alterations of light. Yellow-green eyes become grayish-blue in coming from a dark room into the light. Observations on a large number of school-children showed that as a rule the color of brown or blue irides becomes lighter. Dilatation of the pupil causes a rearrangement of the stroma cells, and the tissues become darker through the tension.

The Blood Circulation.—Dr. Hürthle of Breslau discussed the present status of the doctrine of the circulation and its problems. The course and direction of the circulation are known as well as its motive power, the heart; but the rate of the flow, the resistance encountered, and the force expended are not yet determined. In a series of observations on dogs the relations between pressure and capacity of the aorta have been determined, and the groundwork for future investigations has been laid.

The Blood Ferments.—Dr. Jolles of Vienna described his discovery of ferments in the blood whose property it is to separate oxygen from oxyhemoglobin, and which he calls katalases. In health the quantity of these bodies present is large, but in tuberculosis, nephritis, and carcinoma, it is greatly diminished. Different animals show parallel relations between the amount of katalases and the intensity of oxidation.

The Human Stomach.—Dr. Hasse of Breslau read a paper on this organ, in which he described the form, position, and method of closure of the human stomach, and discussed the anatomical factors explaining regurgitation in children, the difficulty of vomiting in adults, and the direction of the food currents in the full and the empty stomach.

Fowl Tuberculosis.—Dr. Lydia Rabinowitsch of Berlin read a paper in the Section on Hygiene, discussing the relations of this disease to mammalian tuberculosis. After Koch's statement of the non-identity of human and bovine tuberculosis, it was in order to determine whether avian tuberculosis were also independent. The resources of the Berlin Zoological Garden were employed, and of over two hundred birds of different species it was found that twenty-five per cent. had tuberculosis, mostly of the abdominal organs, but, to a greater extent than is usually supposed, of the lung also. Infection usually occurred through the fæces, or through devouring rats or mice affected with avian tuberculosis. Avian tuberculosis, therefore, may be found among mammals, and, on the other hand, it was found that two eagles had died of mammalian tuberculosis. The cultural and pathogenic properties of the separate varieties are different, but transitional forms

may be observed, and the author believes that they are all only varieties of a single species, and that reciprocal infections between birds and mammals take place oftener than is supposed.

Acute Respiratory Diseases, Especially in Childhood.—Dr. Ascher of Königsberg read this paper and called attention to the fact that the deaths from this cause are increasing among infants and the aged. Variations of temperature, especially on successive days, are of great importance. Also the general employment of hard coal as fuel, for smoke even more than soot is injurious to the respiratory organs, especially in damp weather. Ventilation of dwellings is of great prophylactic importance.

Orleans Parish Medical Society.

At the regular semi-monthly meeting of this Society, held July 9, 1904, Dr. Henry N. Blum read a paper, entitled "Ainhum, Report of a Case, with Radiograph." (See page 651.)

Dr. E. L. McGehee, Sr., read a paper on "An Unusual Case of Tuberculous Meningitis." The location of the tubercles rendered the diagnosis very difficult. They were not upon the base of the brain, as usual, but upon the convex surface. They were chiefly upon the inferior or third frontal sinus, the speech centre, which rendered the patient absolutely speechless for days before other symptoms were manifest. As the case progressed the disease invaded the superior portion of the cerebral convolutions, causing contraction, first of the toe, foot, ankle, and knee, and then of the wrist and elbow. The facial muscles were never influenced. There was partial hemiplegia of the left side, yet these muscles would respond to touch. The right arm and leg were constantly in motion, in a state of clonic contraction. At the beginning it was hoped that the cause that produced those unusual symptoms was excentric. Various possible exciters of reflexes, such as adherent prepuce, swollen gums, and alimentary disturbances, all received attention, without result. At one time all the symptoms improved, which gave the friends great hope for a favorable termination, but a relapse soon occurred. As far as could be ascertained the little patient was exempt from any hereditary tendency to tuberculosis. He was strong and vigorous up to the onset of the fatal attack. His nurse had pulmonary tuberculosis; she was fond of the little fellow and kept him in her lap a great deal, and in the opinion of the writer she was the source of infection. Certainly it is no mere coincidence that a child previously healthy, without hereditary tendency to consumption, having been constantly in contact with a tuberculous adult, should die of the disease. This should prove a warning to parents to employ none but physically sound nurses.

Dr. A. Jacoby read a paper, entitled "Treatment of Tetanus." He said that there were five methods of treatment. The result of any treatment should be judged by its effect in acute cases. He felt that, judging by the results, as indicated in the report of successful cases by the intraspinal method, this was the one which was to be preferred. The only question involved was what could be done with those patients whom the family would not permit to be removed to a sanatorium or a hospital. He felt, however, that in those cases one was justified in following this procedure, even under adverse conditions in a private home.

Chicago Medical Society.

At a meeting of this society, held May 11, 1904, a number of cases were presented by Drs. Emil Ries, Frank S. Churchill, and Robert B. Preble. Dr. Geo. Rubin read a paper entitled "A Chief Predisposing Cause of Appendicitis; Preliminary Note, with a Few Laboratory Experiments." After reporting a case of this disease, he detailed some experimental work. The technique was as follows: Portions of bowel, about 50 cm. long, including cæcum and appendix, were resected from subjects dead of other diseases than what would affect that part of the intestinal tract. Specimens from very recent post-mortems were more desirable, but were not always obtainable. After cleansing the piece of bowel, the colon end was ligated; shot, peas, and beans were introduced through the ileum end and the bowel was manipulated so as to indicate more or less peristalsis. The rolling of those bodies was often done with more vigor than normal peristalsis would do. It was observed that none of the contents entered the cavity, although the appendix was held at the most dependent point. Then the bowel was inflated, still containing those substances, the same process of rolling again gone through, with the result that in all the experiments, with one exception, in which only one small shot entered, owing to a highly hypertrophied appendix wall and constricted lumen, the appendical cavity was filled with shot and in two cases peas of medium size gained entrance there. Ten such experiments were carried out. The appendix was readily ballooned during the process of inflation. It is reasonable to suppose, said the author, that similar phenomena might occur in the living. Fitz recorded nineteen out of 267 cases of appendicitis which were supposed to be due to indirect violence. Such cases can only be explained by the fact that a larger mass of fecal matter is forced through the cecoappendicular orifice than the appendix is able to expel, and then trauma to the mucosa, with subsequent infection, takes place. It is not improbable that heavy labor, such as lifting, may operate in a similar manner, *i.e.*, by the increasing intra-abdominal pressure produced by tension of the abdominal wall. These considerations help to explain the marked disproportion in the sexes. Regarding the size of the obstructing mass, no definite statement can be made. The calibers of appendices vary very much. What would be an insignificant particle for one may completely obstruct another. As to the rôle the valve of Gerlach plays in preventing matter from entering the appendix, little could be said, as in all the specimens of bowel the author had examined, in only one was there a lengthening of the mucosa that might have been called a valve. Under ordinary circumstances, the mucous lining itself is sufficient to act as such. The author quoted Van Zwalenberg, of California, who has recently published several series of experiments in which he showed that obstruction is the chief factor in the production of appendicitis, but he considers the subsequent distortion of the appendix with fluid, which impedes the circulation, to be the essential cause. It seems that the circulation of the appendix might be more readily interfered with from an inflammation of the lymphoid tissue in which the appendix is especially rich. Distention of the appendical cavity with fluid takes place rather gradually, and symptoms of that disease do not come on very abruptly; furthermore, cysts of the appendix are not very uncommon and are seldom associated with inflammation of that organ. The author found one in the course of several experiments where the distal half of the appendix contained a considerable amount of fluid, with no other abnormal changes. He did not attach much importance to Clado's discovery of a special peritoneal fold connecting the ovary and appendix, which is supposed to contain an extra blood supply, to explain the disproportion in the sexes. Even if that were a constant anatomical structure, it would not at all explain it, first, because the main trunk of the blood supply is seldom primarily affected; usually the smaller branches and the capillaries are first affected by the inflammatory process within the appendix wall. Second, the rarity of the disease in male infants and very young boys and in old men can hardly be explained by an appendico-ovarian ligament. Before the question is definitely settled, the author believes that experiments on living animals will have to be tried.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 15, 1904:

	Cases.	Deaths.
Measles	52	6
Diphtheria and Croup	275	26
Scarlet Fever	109	8
Small Pox	1	.....
Chicken Pox	26	.....
Tuberculosis	320	157
Typhoid Fever	140	26
Cerebro-Spinal Meningitis	.....	13
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	923	236

The Use of Electricity in Skin-Grafting.—John D. Rushmore, from a study of seven cases, is convinced that we have in this method of grafting a fairly certain way of fixing the grafts. It certainly coagulates the blood and secures the graft in its new position. He doubts the benefit of the secondary application of the Roentgen rays, and is not convinced that the healing process goes on any more rapidly than with any other treatment after fixation of the graft.

A Study of Electrical Injuries.—H. L. Staples divides electrical injuries into three classes: (1) Burns of greater or less severity; (2) Almost instant death; (3) Psychical or functional disorders. The location of burns is most often on the hands; next the wrists, forearms, feet, and legs. The burns are always more severe than apparent on first examination. A slight blister may develop sloughing to the bone. The character of the burns is first dry, aseptic, and indolent, later oozing, while symptoms of moist gangrene may appear. There is often severe pain. The burns should be washed with hydrogen peroxide or some other weak antiseptic, and dressed with protective rubber-tissue strips and cotton. Lard or vaselin ointments are not to be used at first. Skin-grafting, or even amputation may be necessary. A blister should be opened at once. A direct current burns more severely, especially at the positive pole. Extensive burns increase the resistance and are probably a protection. The writer has never seen permanent injury in the case of flash burns or injuries to the eyes by exposure to intense light. The treatment should consist of cocaine, boric acid, and smoked glasses. The severity of the burn is influenced by the completeness and length of contact, the resistance of the body, and the strength and direction of the current. Currents through the thorax, or from head to thorax, are most dangerous. The nervous system does not generally show any pathognomonic post-mortem evidence. Currents of great intensity may cause death by producing a heat coagulation of the cellular constituents. Apparent death should be treated by plenty of air, strychnine, and artificial respiration. Rhythmical traction of the tongue should be kept up. Massage over the heart is indicated. It is well to surround the body with hot water bottles. Efforts should he continued for hours. Electric currents are very apt to induce functional nervous disorders from fright, but it is not probable that they cause organic disease. The effect of confidence, encouragement, suggestion, and isolation is powerful and the only way to promote speedy recovery. A patient cannot get well while litigation is progressing. The older the patient the greater the danger of chronicity. In some cases the neurosis may continue in spite of the best environment and medical care, but these are very rare.—*Northwestern Lancet*

The Trophic Disturbances of the Fifth Pair of Nerves.—Harold N. Moyer advocates the use of castor oil in cases of this kind. The group of cases in which there is vasomotor disturbances includes the greater number of cases, and it is these which especially show the good effects of castor oil. The writer believes that two-thirds of the cases will be benefited, and of this number one-half will be almost cured. At any rate, they will go from 3 to 8 months without a return of the pain. When the pain does return, the same treatment will often result in further relief. A reasonably perfect cure is effected in about one-third of the cases. The explanation of the success of this eliminative treatment is that there is a condition of autointoxication, the presence of some substance in the blood, which this persistent and copious catharsis gets rid of. The writer does not reject the neuritic theory. He believes that there is a certain group of these cases in which the disease starts in the peripheral ending of the nerve, traveling up as a neuritis, and ultimately involving the ganglion. These cases are alone remedied by the surgical removal of the ganglion, or by section of the nerve roots. The writer finally declares that he believes that a large share of the disorders, both trophic and painful, of the fifth nerve have their origin in the teeth. He urges dentists, who see the teeth first, to broaden their clinical investigation of cases, and to look carefully for trophic disturbances about the face, which may be due to the conditions that are taking place in the mouth.—*Medicine.*

Health Report.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General Public Health and Marine Hospital Service during the week ended October 15, 1904:

SURGICAL REFLECTIONS ON THE DIAGNOSIS OF CANCER OF THE STOMACH.*

BY ARPAD G. GERSTER, M.D.,
NEW YORK,
SURGEON TO MT. SINAI HOSPITAL.

IN observing the phases of the process by which new fields of useful activity are conquered to modern surgery, we find a certain regularity in the sequence of events. A study of this process may serve as an introduction to the consideration of the subject proper of this paper.

We find, that as to the abdominal contents and their maladies, the definitive settlement of the diagnostic problems bearing upon and determining actual practice, has very often been accomplished by surgical exploration of the field of disease, that is, by what has been aptly characterized as the "autopsy on the living subject."

What the ultimate or fatal lesions of any serious disorder are, we have been abundantly taught by the findings on the post-mortem table. These findings have generally served adequately to explain the clinical symptoms preceding more or less immediately the fatal issue. These well-known and easily interpreted symptoms, however, do not, as a rule, present themselves in their full significance, until the life of the patient is so irrevocably compromised that surgical interference has become nearly or entirely hopeless.

What the practitioner needs is a recognition and sound interpretation of the symptoms to be observed during the *initial stages of the disorder,* by the aid of which the enterprising, but conscientious, surgeon may be enabled to take the active measures at a time when the inherent conditions are still, and in an overwhelmingly hopeful manner, favoring curative success.

There is nothing that has done more for the elucidation of the pathological bases of the early symptoms of a number of important maladies than exploratory incision. It has enabled us to study pathological fact and physical symptom, as it were, together, and by the exploratory incisions of the early practitioners of the antiseptic method, a more important advance has been achieved in the diagnostics of certain maladies, than by any other known means.

As an invariable result of these explorations in vivo, we have seen to follow such an enrichment of our diagnostic apparatus, such an increase in precision of diagnosis, that the steady diminution of the necessity for the "autopsia in vivo" is, in consequence, becoming more and more apparent.

*Read by invitation before the Harlem Medical Society, June 1, 1904.

All this was, and could be, brought about only by the priceless immunity that was bestowed on surgery by the antiseptic method.

Now let us illustrate these statements by historical facts.

The genius and daring of Richard Volkmann shed the first rays of useful light upon the early phases of the various forms of osteomyclitis and of arthritis, and this by means of bold exploration.

Not a few of you will, perhaps, remember the din and noise caused, about twenty years ago, by the disputations of the gynecologists about the proper significance and treatment of what then was called pelvic peritonitis. The tumult and confusion was only stopped by the many exploratory incisions of such men as Lawson Tait, Noeggerath, and others, who demonstrated the tubal or ovarian origin of the infection of the pelvic peritoneum. Likewise, the causation of pelvic hæmatoma was cleared up by the same means. Nowadays even the tyro will not fail early and properly to diagnosticate tubal and ovarian suppuration, or extrauterine pregnancy.

An exactly similar history can be told of the disorders of the appendix vermiformis, the nosology and diagnostics of which were firmly placed on a workable basis by the efforts of Sands, Weir, and McBurney.

Another group of cognate disorders, those of the biliary tract, owe the highly developed state of their diagnostics and surgical therapy mainly, if not entirely, to the exploratory work of such men as Courvoisier, Riedel, Langenbach and last, but not least, to Kehr. Here, too, early and frequent bloody exploration laid the foundations of present diagnostic possibilities, led to the acquisition of therapeutically useful knowledge, that is, to the logical interpretation of hidden pathological fact by the observation of clinical phenomena.

Let us now turn to a field, the proper subject of this paper, the cultivation of which is certainly full of great promise.

Here, too, the main impediment to substantial progress is the uncertainty of diagnosis. With the hands of the diagnostician strengthened, little difficulty would be encountered by the surgeon to induce patients afflicted with cancer of the stomach to submit to an early operation. For, while on the one hand the malady means inexorable death, on the other we know that the chances of a radical operation, if taken early, are to-day not only not bad, but very good indeed. And though this refers in the main to the chances of immediate recovery from the operation, it must undeniably influence the prognosis of recurrence also.

The limit of the time at our disposal forbids bringing forward statistics to prove the first proposition. Be it sufficient to say, that the mortality of

the operation for pyloric, the most common form of cancer, has, ever since the operation was first done by Billroth in 1880, steadily declined. At first it was over 50 per cent.; to-day, for instance, in the case of Mayo, it has reached a fraction more than 18 per cent. This improvement is due not only to the development of a simple and safe technique, in which the saving of blood, of time, and the security from infection are the main factors, but also to the increasing inclination of surgeons to operate early, and of patients to submit more readily to an operation.

Billroth and his immediate followers did not operate except upon patients in whom the presence of a gastric tumor interpreted the clinical symptoms as those of cancer. A great proportion of these cases is, as we know, very far gone. It is far gone, both as to deterioration of the general health, and as to the involvement of adjacent parts. Originally these operations demanded between two and a half to three and a half hours' time, were invariably followed by a deep shock, and by a high mortality. How matters have improved in this respect, let me illustrate by a quotation from William J. Mayo (*Annals of Surgery,* March, 1904, p. 330). He says: "If the patient is in good condition, there is practically no shock, because there is no blood loss, and little exposure of abdominal contents, the operation proceeds systematically, and can be done, in a suitable case, by the average operator, from the beginning of the abdominal incision, until it is closed, in from fifty minutes to one hour and fifteen minutes."

While it is then true that the technique of the excision of gastric cancer has attained very great perfection, can the same be said of the means for establishing the diagnosis of the malady at its early stage? In spite of the persistent efforts of a large number of brilliant minds directed towards the object, the question must be answered in the negative.

Let us now briefly review the diagnostic apparatus, such as it is to-day.

The initial local symptoms are very vague and present nothing characteristic. When a middle-aged person, whose digestion had always been irreproachable, is suddenly and without known cause afflicted with a rebellious dyspepsia, a certain suspicion is justified; but this form of onset is the exception rather than the rule. Age, though a valuable factor, is not absolutely characteristic. Lack of appetite, though the rule, is not without notable exceptions. Bulimia, that is, an insatiable appetite, has been repeatedly observed. Thirst is only present when gastric motility is much impaired. Pain is inconstant, tenderness also, and the former is paroxysmal only in the presence of pyloric obstruction, and terminated on vomiting or on artificial depletion. The presence of blood in the gastric contents in small quantities is not characteristic. Coffee-ground vomit is frequent, and although somewhat more significant has no absolute diagnostic value. The swelling of the cervical glands is very rare, that of Virchow's gland, a late and inconstant symptom. We shall dispose of the systemic symptoms and their significance by stating that they are terminal, that is, they become manifest only when the malady is approaching its fatal end.

Now let us see what can be said of the function of the stomach in cancer.

Constant absence of free hydrochloric acid is frequent, and may almost be said to constitute a rule. But where the cancer is developing on the basis of a gastric ulcer, the rule suffers many exceptions. Moreover, absence of free hydrochloric acid accompanies fever, amyloid degeneration, cardiac troubles, phthisis, and essential atrophy of the gastric mucosa.

Absence of the digestive ferments is also an inconstant phenomenon.

The presence of lactic acid depends on three factors; first, on the absence of free hydrochloric acid; secondly, on the presence of motor insufficiency, and thirdly, on the diminution of the digestive ferments and of the digestive capacity for albumin. It is one of the most significant symptoms, and exists, according to Strauss, in 91 per cent of all cases of gastric cancer. But, on the other hand, the symptom is present in a number of other morbid states, such as are gastritis gravis, mucous atrophy, benign pyloric stenosis, then in cardiac, renal, pancreatic, and some intestinal disorders, such as, for instance, invagination. Moreover, it is a very late symptom, and, in the absence of the three cardinal factors just mentioned, fails utterly, though cancer be present.

Before quitting the subject of chemicity, let us glance at some of the more recent researches bearing upon it. Siegel (*Berliner klinische Wochenschrift,* 1904, Nos. 12 and 13), who re-examined the work of Salomon (*Deutsche medizinische Wochenschrift,* 1903, No. 31) and Glazinsky, bases his argument on the well-known fact that most gastric cancers can be classed in two groups: one containing those situated on the lesser curvature, and not complicated by pyloric stenosis, the other made up by the carcinomata that occupy the pyloric portion, and are most frequently accompanied by motor insufficiency due to stenosis.

The well-known fact that the surface of open cancers is secreting albumin, was utilized by Salomon, who, after withholding albuminous food, and the subsequent employment of carefully arranged washings by a saline solution, demonstrated the frequent presence of free albumin in the contents of the cancerous stomach. Sigel confirms this finding absolutely in carcinomata of the lesser curvature without stenosis, but rejects it in cancers developing on an old ulcer located near the pylorus. He finds that in these cases even small quantities of the free hydrochloric acid, which is frequently present, will digest the free albumin.

Glazinsky's thesis may be stated thus: When a hyperacid gastritis is followed by a mucous gastric catarrh, this may signify one of two things: Either that an ulcer has healed and a coexistent pyloric contraction has disappeared (for the persistence of the contraction would have caused the persistence of hyperacidity); or, that a pre-existent ulcer is undergoing a cancerous transformation.

It would transcend the limits of this paper to enter into the proofs brought forward by Glazinsky, which must be looked up in the original paper, and it may suffice to quote this as his conclusion, that with a history of ulcer and stenosis, increasing secretory insufficiency forms a strong indication of the presence of cancer. Inversely, where in the course of an ulcer, and in the absence of pyloric

stenosis, a tumor appears, and with all this there is no constant diminution in the secretion of free hydrochloric acid, cancer can be excluded with certainty. The writer of this paper has recently had occasion to verify the value of this thesis in a case at Mt. Sinai Hospital, and Sigel himself quotes a very striking case of his own, admitting the relative value of Glazinsky's method. He states, however, at the same time, that he has seen the method fail utterly.

Now let us see the value of the microscopic examination of the stomach contents. As said before, blood is very frequent in small quantities, but is just as often present in benign ulcerations. The Boas and Oppler bacillus (successfully cultivated by Kaufmann and Schleringer), is frequently found wherever, from whatever cause, lactic acid is abundant. Hence it is not pathogenomic. Cancer particles have a positive value, but are exceedingly rare.

In cancer, gastric motility is, as a rule, somewhat depressed, even where there is no pyloric stenosis; but marked disturbances of motor power are observed only when there is pronounced pyloric obstruction. According to Schüle, this is found only in 13 per cent. of all cases of cancer.

Neither examination of the blood, nor of the urine, yields any important aid towards the making of the specific diagnosis. Rosenfeld's assertion, that in cancer of the stomach the volatile fatty acids became augmented in the urine, is positively refuted by Sigel.

The presence of a gastric tumor may be of the greatest significance, but here again much difficulty is encountered. There are flat, diffuse forms of gastric cancer, which never develop a tumor. Then, in the presence of a tumor, it may be difficult, even impossible, by means of most skilful palpation, by the added inflation of stomach or colon, or by both, and even under anæsthesia, positively to determine whether the tumor is one of the stomach or not, not to mention the cases where an existing tumor cannot be felt on account of its high and hidden situation behind the costal arch or the liver, or where satisfactory palpation is utterly impracticable on account of meteorism, spasm of the abdominal muscles, ascites, or the presence of great masses of bellyfat.

The *respiratory and passive mobility* of the tumor, or their absence, are also phenomena not always easy to ascertain or to interpret, and *local tenderness on pressure* depends mainly on inflammatory conditions which may complicate cancer, or exist without it.

These are the main facts bearing on diagnosis in general, and, as you see, presenting much that is perplexing. Now, let us see how it is about the early diagnosis? Difficult as the diagnosis often is, even in much progressed cases, it is much more so in the initial stages of the trouble, that is just when active surgery might still be successful. The status of the question can be better characterized by two quotations, one from Czerny, the other from Kraske. Czerny says that "cancer of the stomach should not be operated upon radically at a time when its recognition as a tumor has become certain," and Kraske's words are as follows: "Operation for pyloric cancer is desirable only when a tumor cannot be felt, and when, on this account, no positive diagnosis is possible" (*Berliner klinische Wochenschrift*, 1894. Nos. 20 and 21). Thus we are placed here before an irreconcilable contradiction! On general principles we ought not to operate without a positive diagnosis; on the other side, however, we see that the dicta of such weighty authorities as Czerny depreciate operating at a time when the diagnosis has become plain, thus erecting the postulates clearly expressed by Kraske, that cancers ought to be operated upon before they can be certainly recognized as such.

Let us make an attempt to see whether the harsh contradiction in terms of these two postulates cannot be softened by the aid of differential diagnosis.

Eliminating the symptom of tumor, we have to depend on two things. First, on the dyspeptic disturbances, and, secondly, upon symptoms due to the damage done to the general condition.

Let us appeal to the method of exclusion to see how far it is able to help us.

In reference to the disturbances of the gastric function, first all those maladies must be excluded, which, like gastric cancer, are accompanied by marked diminution or absence of free hydrochloric acid. They are:

1. The chronic catarrh of the stomach.
2. All the processes other than cancer that lead to atrophy of the gastric mucosa.
3. Certain gastric neuroses.

A chronic catarrh will show a lengthy course, with ups and downs, with moderate and temporary diminutions of the free hydrochloric acid, and no grave impairment of the general condition; whereas the sudden appearance of rebellious dyspepsia, without adequate cause, in a person of previously faultless digestion, with coffee-ground vomit, with constant and increasing diminution of free hydrochloric acid; then the appearance of lactic acid, accompanied by grave emaciation, will certainly justify the strongest suspicion of cancer.

Not only grave and pertinacious catarrh, but especially that form of mucous atrophia dubbed by Ewald "anadeny," can determine such an alarming state of cachexia, that the suspicion of cancer will become very obvious. Such atrophy appearing in consequence of a chronic or toxic gastritis, or as an essential and independent malady, will have a very protracted course, and will not be ordinarily complicated by disorders of motility. Likewise shall we rarely observe motor insufficiency in forms of atrophy due to the presence of cancer of the œsophagus, duodenum, rectum, of the mamma, the uterus or the peritoneum, and notable variations will be observed in the state of the gastric secretion in different stages of the process. The only exceptions to this rule occur in cases of duodenal cancer when motor disorders and the presence of lactic acid are frequent (Ewald).

The greatest difficulties, however, will be encountered in the differentiation between cancer of stomach, and between atrophy due to gastric distension, caused by benign stenosis of the pylorus. It is pertinent to mention here the clinical conception maintained by Einhorn and Martius, under the name of simple gastric achilia, the necessity for which, however, is much questioned by various authors.

We have finally to bring forward certain neuroses of the stomach, that also can be the cause of very grave forms of atrophy, difficult to recognize, and

still more difficult to defferentiate from cancer, developing on the basis of an old gastric ulcer in a neurasthenic individual.

As to gastroscopy and skiagraphy, neither has yielded anything really valuable to aid the early diagnosis of gastric cancer, and, as to the significance of the etiological factor of traumatism, the most discouraging divergence of opinions has to be noted.

We see, then, that with our present knowledge a reliable diagnosis of incipient cancer of the stomach is a sheer impossibility.

Thus we are brought again face to face with the dilemma contained in the words quoted above from Czerny and Kraske.

Heretofore sound practice has demanded that a patient be not subjected to the risks of an operation without a clear knowledge of the diagnosis. Only in exceptional cases of great urgency was it permissible to resort to probatory incision. But keeping in view what we had to say about the uncertainties of the diagnosis of gastric cancer, especially in the early, operable stages of the malady, every suspected case of cancer of the stomach constitutes an urgent case. The fact is that while, after having conscientiously exhausted all means of diagnosis in cases of trouble affecting the appendix, the uterine adnexa or the biliary passages, we do not hesitate to resort on suspicion to the diagnostic incision, it is not less a fact that we still hesitate to do so in the face of a more certainly deadly malady than those mentioned; that is, in suspected cancer of the stomach. For we know that a respectable proportion of the infectious disorders of the organ just mentioned can be and are cured by the maiden efforts of nature; but the only possible issue of a gastric cancer is death. Why, then, hesitate to urge probatory incision at a time when the risk connected with it is slight and when, with its diagnosis early established, cancer can be surgically attacked in the only known manner that promises success.

The objections to operating, in this field on suspicion "are less real than imaginary," whenever the suspicion is well grounded in the results of careful clinical observation and experience. The repugnance of the patient is very often merely the outcome of the repugnance and lack of initiative in the physician.

Our appeal is necessarily directed to the zeal and energy of the general practitioner, who has the first chance to suspect the presence of gastric cancer, and upon whose intelligent and conscientious initiative depends the ultimate success of all operative measures.

In the case in question, the principle, that we must not submit a patient to the risks of any operation until the diagnosis is well secured, is led *ad absurdum* by the hard facts just brought out. Blind adherence to it means that no case of gastric cancer can be attacked by the surgeon, for in its initial stages no diagnosis can be had, and, further, because, *when* the diagnosis has become apparent, the malady is beyond surgical help.

The absurdity of this position will be still more apparent when we consider that, even in the presence of all the known late symptoms, local and general, of gastric cancer, no conscientious diagnostician can positively assure the patient that his malady is indubitably a case of cancer.

In view of the great variations observable in the malignity of the several histological varieties of gastric cancer, the ultimate prognosis as to recurrence will necessarily be *pari passu* different in different cases. It is safe to predict that the greatest successes will be achieved by early operations done on those forms of cancer which show the least tendency to rapid dissemination.

In conclusion, we may summarize our argument in this sentence:

When in a clearly progressive case of an intractable disorder of the stomach the local and general symptoms, conscientiously collected and weighed, strongly justify the suspicion of cancer, diagnostic laparotomy should be considered not only admissible, but obligatory.

CONDITIONS SIMULATING AND MISTAKEN FOR ACUTE APPENDICITIS.*

By HENRY ROTH, M.D.,
New York,
Assistant Attending Surgeon, Lebanon Hospital.

The diagnosis of acute appendicitis is made without difficulty, in the great majority of cases. Nevertheless, cases of appendicitis are frequently overlooked, or appendicitis is diagnosticated where some other condition is present. The most constant symptoms of acute appendicitis are a sudden onset of abdominal pain, tenderness, rigidity, nausea, vomiting, and rise in the pulse rate and temperature. This chain of symptoms, however, may be caused by other pathological conditions, and unless the fact is borne in mind, mistaken diagnoses are liable to occur. Considering the multiplicity of tissues, and their liability to inflammation, it will be readily seen that there are many conditions which might simulate, and be mistaken for appendicitis.

It is beyond the scope of this paper to enumerate all the various tissues and organs which might be involved. In every case, with symptoms pointing to the right lower quadrant of the abdomen, the history and symptoms should be carefully considered, and the possibility kept in mind of some condition other than appendicitis. A diagnosis of appendicitis should not be made unless all other possible conditions have been excluded. At times an absolute diagnosis will be impossible, in spite of care and study, and only laparotomy will reveal the true condition. In many of the conditions mistaken for appendicitis, operation is quite as necessary as in appendicitis. In those cases in which general peritonitis is present, it is frequently impossible to say where the primary infection originated, but here the existing condition necessitates prompt operative intervention. During the past two years a number of cases came under my observation in which a diagnosis of acute appendicitis was made in the presence of some other condition. These cases have been of greater instructive value than a greater number of typical appendicitis cases. In addition to a report of the histories, I will briefly allude to the most important points in the differential diagnosis.

Case I. Adele F., age 36 years, married, was admitted to the Lebanon Hospital on February 6, 1903. For the past eight years she had occasional attacks

*Read before the Medical Society of the Borough of the Bronx.

of a sense of pressure in the lower part of her chest, which would last for several days at a time. Nine months ago she had an attack of pain in the right side of her abdomen, chills, fever and vomiting. She was treated for malaria, and remained in bed for a week. Subsequently she had a similar attack, which kept her in bed for two weeks. She was never jaundiced. Her present illness began eight days ago, with pain in the right side of her abdomen. The pain grew worse four days ago. She vomited once and her bowels moved after cathartics. She was sent to the hospital for operation, with a diagnosis of acute appendicitis. On examination, tenderness and rigidity was elicited over the right rectus muscle about the level of the umbilicus. An indistinct mass could be felt through the rigid muscles in the region of tenderness. The mass moved up and down with respiration. Tenderness extended below the level of the umbilicus, and almost to the median line. Her pulse was 116, temperature 101.4° F., and leucocytosis moderate. There was no jaundice, no vomiting, and nothing abnormal in the fæces or urine. The region of the appendix was somewhat tender. All the physical signs pointed to the region of the gall bladder, and the diagnosis was changed to acute cholecystitis, with calculi. She was operated upon by the writer on February 7, 1903. Through an incision of the right rectus muscle a tense mass was exposed. This proved to be the distended gall bladder, and was about the size of an orange. This mass was distinctly palpable through the abdominal walls, under full anaesthesia. There was localized peritonitis. The gall bladder was first aspirated and then sutured to the parietal peritoneum, in the upper angle of the wound. On opening the gall bladder a quantity of thick, muddy bile escaped, and the walls were about one-quarter of an inch in thickness. In all eighteen calculi were removed, varying in size from a hazelnut to a pea. Several of the calculi were removed from the cystic duct. A drainage tube was inserted and the rest of the wound sutured. There was at first a free discharge of bile-stained mucus, but it rapidly diminished and no bile escaped, showing that the cystic duct was still obstructed by a calculus. She improved rapidly, and declined further operation for the relief of the obstructed cystic duct. She left the hospital on March 12, 1903, feeling perfectly well, but with a very fine sinus, discharging mucus.

In this case the symptoms pointed to appendicitis, but the physical signs were those of cholecystitis. Nevertheless, we must bear in mind that the gall bladder in this case was situated much lower than is usual, and that pain and tenderness in appendicitis might be on as high a level as it was in this case, especially, if the appendix be pointing upwards. Examination showed the mass to move up and down with the movements of the diaghragm; this phenomenon is not observed in appendicitis.

These two conditions have many symptoms in common, and literature contains many reports in which cholecystitis was mistaken for appendicitis. Not infrequently we are able to elicit a history of attacks suggesting biliary colic, or a history of indigestion. The pain in cholecystitis is, as a rule, on a higher level, and radiates to the back. It is often referred to the epigastric region, which is exceptional in appendicitis after the first few hours. The maximum point of tenderness after the first twenty hours of cholecystitis, is just below the border of the ribs. Cholecystitis is usually caused by impaction of a calculus in the cystic duct. This obstruction is usually complete, and prevents drainage of the gall bladder, which in time is followed by increased secretion of mucus, and hence, distention of the organ. In the diagnosis of cholelithiasis, entirely too much stress is laid upon the presence of jaundice. Where only obstruction of the cystic duct is present, as in the majority of cholecystitis cases, jaundice is absent. A distended gall bladder without jaundice points to obstruction of the cystic duct. In fact, most attacks of so-called biliary colic are not associated with jaundice, because in reality they are attacks of cholecystitis.

Case II. Sadie E., age thirteen years, was admitted to Lebanon Hospital on September 28, 1903. For about a month she had had more or less pain in the abdomen, lasting three to four days at a time. About five days before admission, after returning from school, she was seized with pain about the umbilicus, which lasted for about four hours. After this she had more or less pain, on the right side, particularly at night. The point of maximum tenderness was in the right iliac region, but somewhat above McBurney's point. At this point a distinct mass was palpable, which on account of its tenderness could not be examined very thoroughly. Her temperature was 101°, pulse 110 and respiration 24. After a diagnosis of appendicitis, the abdomen was opened over the most prominent part of the mass, which under full anaesthesia appeared to be hard, and the size of a chicken's egg. The appendix was normal, and was in no way connected with the tumor, which was fluctuating and proved to be part of the right kidney. Aspiration revealed clear fluid; therefore, the diagnosis was changed to hydronephrosis. I incised the posterior layer of the peritoneum external to the colon, and exposed what proved to be the distended pelvis of the kidney. The posterior layers of peritoneum were partly sutured to the anterior abdominal wall, and the rest of the peritoneal cavity was walled off by gauze tampons. The pelvis of the kidney was incised, and about two ounces of clear fluid evacuated. Before completing the operation I endeavored to find the cause of the obstruction. The ureter was permeable, and at the time showed nothing abnormal. Drainage was followed by a free discharge of urine which gradually diminished and stopped entirely. The wound healed and she was discharged on October 29, 1903. Six months later she reports in perfectly good condition.

This, undoubtedly, was a case of intermittent hydronephrosis. The kidney was below its normal level, consequently the distended pelvis was palpable at a point where an exudation due to a postcaecal appendicitis might be found. Urinary symptoms were not observed. The history of similar attacks was considered to be in favor of appendicitis. What the exact cause of the obstruction was could not be determined; it may have been kinking of the ureter in connection with a displaced kidney, or a congenital faulty implantation of the ureter.

Case III. William M. G., age forty years, single, was admitted to Lebanon Hospital on February 6, 1903. Six years ago he had an attack of pain and vomiting like the present one. He remained in bed

for a few days and recovered without medical aid. On February 5, while at dinner, he felt a sudden pain, dull and rolling in character, most of the pain being in the right iliac region. The pain became gradually worse, and he could not sleep on account of pain and incessant vomiting, which began soon after the initial attack of pain. Vomiting continued all night and the next day. Bowels moved several times on the following day. During the night he was seen by his physician, who sent him to the hospital with a diagnosis of appendicitis. When he arrived at the hospital his temperature was normal, pulse 88, respiration 24. On examination, a distinct movable mass was palpable in the right iliac region. There was rigidity and considerable tenderness over the right side of the abdomen. Abdomen was somewhat distended. After admission to the hospital, bowels moved freely after a soapsuds enema. On February 7, 1903, forty hours after the first symptoms appeared, he was operated upon by the writer. Under ether anaesthesia, the abdomen was opened through a Kammerer incision. On opening the peritoneal cavity, a quantity of serous fluid escaped The appendix was normal. On further examination a movable mass was felt, which proved to be the caecum and ascending colon, with the ileum invaginated. An ileocolic intussusception was demonstrated, and an attempt made to reduce it. This was impossible and resection was performed. A faecal fistula remained, requiring further operative treatment. He left the hospital with a small faecal fistula. For a detailed history of this case, see MEDICAL RECORD, December 19, 1903.

The greatest number of cases of intussusception occur in children during the first year of life. The most important symptoms are a sudden onset of paroxysmal pain, vomiting, and bloodstained stools. These symptoms, in a young child, will readily lead to a diagnosis of intussusception. In adults, primary acute intussusception is comparatively rare, and the symptoms are not quite as characteristic. While in children the diagnosis should rarely present difficulties, in adults the condition is frequently mistaken for some other condition. Literature contains several reports in which intussusception was mistaken for acute appendicitis.

Reviewing the history of our case, several features will be found which pointed against appendicitis. The pulse was not appreciably accelerated, and the temperature was normal. The mass in the right iliac fossa was unusually large for the first forty hours of appendicitis, and was freely movable. On the other hand, we find that the bowels moved freely, even forty hours after the onset of the disease, and there was no blood in the evacuations. The comparative rarity of acute intussusception in adults, was perhaps the main cause for overlooking the true condition, and mistaking this case for appendicitis.

CASE IV. Mamie M., age twenty-one years, single, was admitted to Lebanon Hospital on June 1, 1903. Menstruated last on May 27. Six days ago she began to have pain in the abdomen, which gradually localized in the right iliac fossa. She vomited several times, and her bowels were constipated. Appendicitis was diagnosed and she was sent to the hospital. On admission she complains of continuous pain in the lower right side of her abdomen. Temperature 103.2°, pulse 126. Abdomen is somewhat distended and tender over lower part, and principally on the right side. Rigidity of the muscles is very pronounced over the lower right quadrant. The abdomen was opened by the writer, through an incision along the right rectus muscle. On incising the peritoneum, considerable serum escaped. The peritoneum of the lower part of the abdomen and pelvis was highly congested and covered by a recent fibrinous exudate. This condition was present about the ileocaecal region, and involved the appendix. This was removed, but it was apparent that the peritonitis originated in the pelvis. The right tube was distended and imbedded in a recent exudate of fibrin and serum which filled the entire pelvis. The right tube was removed, the serum and fibrin sponged away and the pelvis drained. The temperature and pulse rate gradually returned to normal, and she was discharged cured, on July 5, 1903.

CASE V. Mary E., age twenty-four years, married, was admitted to Lebanon Hospital on March 21, 1904. Has two children. In 1899 had peritonitis. Last menstruation began on January 18, 1904, lasting five days. On March 15, she aborted in the fifth week of pregnancy, expelling a complete ovum, and remained in bed for three days. She was feeling well until the day before admission; on this day she was taken with abdominal pain and vomiting. Most of the pain was localized in the right iliac region, and was of a dull aching character. She vomited several times; bowels were constipated. On the following day she was sent to the hospital with a diagnosis of appendicitis. On reaching the hospital her temperature was 104.4° F., pulse 100, and she complained of pain in the lower part of her abdomen. Tenderness was most marked slightly above Poupart's ligament and to the right of the median line. Rigidity was slight and there was no exudate around McBurney's point. Vaginal examination revealed tenderness to the right of the uterus, and a circumscribed mass, most likely a pyosalpinx of the right tube. There was no fetor to the uterine discharge. She was transferred to the gynæcological service, and was operated upon several days later. Laparotomy, performed by Dr. Ralph Waldo, exposed a pyosalpinx of the right side and a normal appendix. The pyosalpinx was removed and the patient made an uneventful recovery.

These two cases illustrate the possibility of mistaking inflammatory diseases of the uterine adnexa for appendicitis. In one of the cases the appendix was involved by the extension of the pelvic peritonitis. Inflammatory diseases of the uterine appendages frequently present symptoms which simulate an attack of acute appendicitis. This is most likely when a pyosalpinx is above the pelvic brim, or a pelvic abscess extends beyond the pelvic cavity. On the other hand, if the appendix extends into the pelvis, which is rather common in women, appendicitis might be mistaken for a pyosalpinx or a pelvic abscess. Should a long appendix be the seat of inflammation, it may become attached to the tube or ovary, and infect it by contact; on the other hand, a pelvic peritonitis may, by extension, involve the appendix. A history of gastro-intestinal disturbances points to appendicitis, while in cases of pelvic inflammation, there will be a history of menstrual irregularity, gonorrhœa, puerperal infection or mis-

carriages. Frequently there is a history of pain and fever occurring simultaneously with menstruation. The pain of acute appendicitis is more acute in its onset, and after a few hours is localized in the right iliac fossa. Constitutional and gastro-intestinal symptoms are more pronounced in appendicitis. In pelvic inflammation the pain is more diffuse, often extending to the opposite side. On vaginal examination, in cases of pyosalpinx, a clearly defined tumor is found. Pain after micturition or defæcation point to pelvic trouble. In pelvic inflammation usually both sides are involved, while in acute appendicitis, if the exudate extends into the pelvis, it is usually more pronounced on the right side. At times an absolute diagnosis is impossible, especially where both conditions are present simultaneously. Where doubt exists, operation is the safest course to pursue.

Case VI. Rose F., age forty years, married, was admitted to Lebanon Hospital on July 5, 1902. She was sent to the hospital with a diagnosis of appendicitis. As far as could be learned, she was seized with severe abdominal pain and vomiting about five days before admission. The pain continued and became most marked in the right lower quadrant of the abdomen. During this time her bowels did not move and vomiting was present from time to time. Her abdomen was very much distended and tender; the tenderness being most marked in the right lower quadrant. In spite of marked rigidity, a mass, the size of a cocoanut, was found, occupying the right iliac fossa. The mass was slightly movable and dull on percussion. The eyes were sunken and showed some icterus. On vaginal examination a tumor was found to the right of the uterus, which on bimanual examination, corresponded to the one felt in the iliac fossa. There was a blood-stained vaginal discharge. Her temperature was 101.2° and pulse 120. There was muttering delirium and restlessness. Bowels were constipated and vomiting frequent. General peritonitis, probably due to torsion of the pedicle of an ovarian cyst, was diagnosed. In spite of the apparently hopeless condition, she was operated upon on July 6, 1902. The abdomen being open, a large quantity of blood-stained fluid escaped, and a dark-red tumor was exposed, which on further examination proved to be a gangrenous ovarian cyst, with a double twist in the pedicle. After evacuating the contents of the cyst, the healthy portion of the pedicle was ligated and the entire mass removed. The abdominal cavity was rapidly sponged out and the wound closed with the exception of the lower part which was drained. In spite of active stimulation her condition failed to improve. Though the bowels moved freely, vomiting continued, delirium became violent, and she died from peritoneal sepsis, three days after the operation.

In this case, although the patient did not come under my observation until symptoms of general peritonitis were present, the physical signs led to a correct diagnosis. At times there is a history of a previously existing tumor. Intense pain and severe abdominal shock are the initial symptoms. This shock is of the greatest diagnostic value, and is rarely present with appendicitis. As the result of the torsion, circulation is interfered with, venous obstruction being most marked. This obstruction to the return flow gives rise to a hemorrhage into the cyst which is followed by a rapid enlargement of the tumor; this is one of the most important signs of torsion. The tumor is extremely tender and hard, and is at the site of the first pain. Signs of internal hemorrhage may develop, and the condition might at first suggest rupture of an ectopic gestation. Unless the condition is promptly relieved, peritonitis sets in as the result of rupture or gangrene of the cyst. In women, a history of sudden pain and marked abdominal shock with a rapidly growing tumor, should suggest acute torsion of the pedicle of an ovarian cyst.

Some years ago I reported to this Society the history of a patient, who was sent to the hospital with a diagnosis of acute appendicitis. A very marked anæmia and the absence of an inflammatory exudate, led me to make a diagnosis of ruptured ectopic gestation, which was confirmed at the operation. Sudden, severe pain, profound shock or collapse, marked anæmia and a low hæmoglobin percentage, with a history of menstrual irregularity, are the most important points in the differential diagnosis.

Case VII. John D., age forty-five years, was admitted to Lebanon Hospital on November 14, 1902. Twenty-four days before admission, he began to complain of severe pain in the lower part of the abdomen. He vomited twice and had some fever. Bowels moved freely without cathartics. Appendicitis was diagnosed and he was sent to the hospital for operation. On admission his temperature was 102.2° and pulse 94. A diffuse exudation was felt in the lower part of the abdomen which extended from a point above the middle of Poupart's ligament on the right side across the abdomen into the left iliac fossa, where it was most pronounced. In the median line, the infiltration extended about three inches above the symphysis. The region of McBurney's point was not very tender, nor was there any rigidity. On the right side the infiltration did not reach as high as on the left, where it extended about four inches above Poupart's ligament. The diffuse infiltration appeared to involve the abdominal wall, which was tender but not fluctuating. The rest of the abdomen showed nothing abnormal. There were no symptoms of peritoneal sepsis. Most of the local trouble was on the left side. This, with the comparative freedom of the region of the appendix, led to a diagnosis of a properitoneal abscess of unknown origin. His physician insisted upon the correctness of his diagnosis; therefore, to set aside all doubt, a small incision was made, and a normal appendix exposed. At the same time a diffuse infiltration of the abdominal wall was demonstrated which was in no way connected with any intraperitoneal organ. The incision was closed and sealed. An incision was then made on the left side about an inch above and parallel to the outer half of Poupart's ligament. After splitting the fascia and muscle fibres, an abscess was opened and a large quantity of thick, foul pus evacuated. The abscess cavity extended towards the right side, and seemed to be principally prevesical. After draining the cavity, he made a perfect recovery.

Case VIII. Kate R., age seven years, was admitted to Lebanon Hospital on July 24, 1903. Six weeks ago she began to complain of pain in the abdomen, but continued to go to school. A week

ago she complained of pain in the right side of the abdomen, and had some fever. The family physician was called in four days later and detected a tender mass in the right iliac fossa. Recognizing the possibility of acute appendicitis, she was sent to the hospital for operative treatment. On admission she was irritable and restless; her temperature was 104° F., and pulse 140. A mass was felt over Poupart's ligament, extending upwards for two inches. It was tender and seemed to be in the abdominal wall. There was no tenderness or rigidity around McBurney's point. There was no vomiting, and the bowels moved without cathartics. A properitoneal abscess was diagnosed, probably due to suppurating iliac lymph glands. She was operated upon by the writer, and after incising the skin and separating the fibres of the abdominal muscles, about an inch above Poupart's ligament, an abscess was opened. The abscess proved to be properitoneal and broke through the deeper layers of the abdominal wall. After the operation a vaginal discharge was noticed, the result of gonorrhœal vulvovaginitis. The discharge diminished and she made a perfect recovery.

In the first of these cases, the abscess developed in the properitoneal space and was, probably, prevesical in origin. In the second case, the abscess was most likely, due to gonorrhœal infection of some of the iliac-lymph glands. In the first case, the slow course of the disease, without any peritoneal symptoms, as well as the diffuse induration of the anterior abdominal wall, without rigidity, pointed against appendicitis. In the second case tenderness was most marked just above Poupart's ligament, and the exudate was in the abdominal wall. There was but slight rigidity and McBurney's point was free from pain. A properitoneal abscess will produce a diffuse, hard infiltration in the abdominal wall, which will be tender, but may not fluctuate until very late in the disease. This induration will extend upwards or to either side, and on rectal or vaginal examination will be found confined to the abdominal wall. Though the skin may show no redness or oedema until late, fluctuation might be detected, early, on rectal or vaginal examination.

Case IX. Emma Q., aged nine years, was first seen by her physician on May 29th, 1903, and gave the following history. On the preceding day she returned from school, complaining of headache, sore throat and pain in her abdomen. Castor oil was given, but was not retained. Vomiting continued and she was unable to retain anything. At the time of the doctor's first visit, the temperature was 103.4°, pulse 120. There was some hyperaemia of the tonsils, so that her symptoms were ascribed to tonsillitis. The pain in the abdomen and the vomiting were ascribed to some indiscretion in diet. Calomel in small doses was followed by tincture of iron. At this time there was no rigidity, but the entire abdomen was tender. On the following day, May 30, 1903, her throat condition was much better, but her temperature remained high, 103.4°, and her pulse rate was 120. She still complained of pain on the right side of her abdomen, and had a slight hacking cough. On the following morning she complained of severe pains all over the abdomen, but tenderness was most marked over McBurney's point. Appendicitis was suspected, with the possibility of some chest condition. I saw the patient at this time and found the symptoms just mentioned. There was also marked prostration, and the face was flushed. Palpation of the abdomen failed to find an exudate. I also found that the tenderness did not increase on continued pressure, and that the abdominal wall became relaxed. The sudden and marked rise of the temperature, the rapid respiration, flushed face, marked prostration and absence of a distinct inflammatory exudate in the abdomen, with previous experience in similar cases, led me to suspect pneumonia. Examination of the chest showed some dullness over the right lower lobe, with some change in the respiratory murmur. The diagnosis of pneumonia was confirmed by the subsequent course of the disease. In a few hours the physical signs became marked, and she passed through an attack of lobar pneumania, from which she fully recovered.

I have selected this case from a series of four which came under my own observation during the past three or four years. Literature contains reports of quite a number of cases, in which pneumonia was mistaken for acute appendicitis. That an absolute diagnosis is, at times, very difficult, may be seen from the reports of cases which were operated upon by experienced and well-known surgeons. This simulation occurs most frequently in children, but may occur in adults. The abdominal pain is referred from the chest along the lower intercostal nerves, and is not uncommon; the possibility of this reflex pain should always be kept in mind. Vomiting is not at all rare in the early stage of pneumonia, and obstinate constipation and tympanitis are frequently very troublesome symptoms of this disease. Several observers note that the abdominal walls relax with each inspiration and that the tenderness disappears under firm pressure by the flat of the hand. The sudden rise of temperature to a high point, the continued high temperature, the rapid respiration, the relaxation of the abdominal walls with each inspiration, and the disappearance of tenderness on deep pressure by the flat of the hand, with the absence of an inflammatory exudate, point against appendicitis. If, with this chain of symptoms, we bear in mind the reflex abdominal symptoms of pneumonia, an error will usually be avoided.

These cases illustrate but a small number of the conditions which might simulate or be mistaken for acute appendicitis, but it is beyond the scope of this communication to enter into a consideration of the others.

663 East One Hundred and Fortieth Street.

The Throat as the Source of Systemic Infection in Acute Rheumatism.—P. Watson Williams presents a few brief conclusions on this subject: Acute rheumatism is an infective disease *sui generis*. There is a true rheumatic pharyngitis or tonsillitis, and it is a primary infection. Rheumatic fever is a secondary infection, due either to the absorption of the products of the infective microorganisms or to the growth of such microorganisms in the tissues, and the infection may manifest itself in arthritis, pericarditis, endocarditis, chorea, bronchitis, pleurisy, alone or in association. In a large percentage of cases the portal of infection is in the fauces or pharynx or other region of the upper respiratory tract, but most often in the oropharyngeal lymphoid ring. There is no proportion between the intensity of the primary local lesion and the appearance or severity of the secondary systemic complications.—*The Bristol Medico-Chirurgical Journal.*

SOME RANDOM CONSIDERATIONS ON TUBERCULOSIS.*

By AUGUSTUS A. ESHNER, M.D.,
PHILADELPHIA.

Although the subject of tuberculosis is a well-worn one, and knowledge of its various phases is pretty well diffused, it can, by reason of its great importance, always be taken up for discussion with advantage and profit.

Being dependent upon a living cause, susceptible, under favorable conditions, of indefinite multiplication, tuberculosis belongs among the transmissible or communicable diseases. The causative bacteria are contained in the lesions, and they may be thrown off with the discharges from the diseased tissues, and thus find their way directly or indirectly into the bodies of previously uninfected individuals. They are especially conveyed through the air, in the form of dust, into which dried sputum is converted, although they may be distributed with the fine spray into which the expectoration is transformed in the act of coughing. Further, they may be contained in the milk and flesh of tuberculous animals used as food. There has been some difference of opinion as to whether tuberculosis is the same disease and due to the identical bacillus as it occurs in man and in animals, but the most recent evidence tends to sustain the affirmative view.

Knowing the cause and origin of the disease, as well as the channels through which it is conveyed, its preventability is established. A further important etiological factor to be considered is the susceptibility or insusceptibility on the part of the individual exposed to infection. The lodgment and presence of the tubercle-bacilli do not alone constitute the disease, which rather represents the reaction between the invading micro-organism and the tissue attacked. Either the seed falls on fertile soil and undergoes multiplication, or it falls on barren soil and then it fails to thrive.

Tuberculosis is, strictly speaking, not an inherited disease. Exceptionally the tubercle-bacilli pass from the maternal blood through the placenta to the fœtus, in which the disease may then develop exactly as it does in extrauterine life. What the offspring of tuberculous parents really inherits is some vice of tissue, some aberration of function, by reason of which a predisposition to tuberculosis is set up. In addition, such children are exposed to the danger of infection through the usual channels in increased degree by reason of their intimate association with victims of the disease. It were a salutary precaution if tuberculous individuals did not marry. At least, a tuberculous woman should not become pregnant, but in the event of pregnancy and successful delivery, she should not nurse her child.

An important aid in checking the spread of tuberculosis is the recognition of the disease in cattle, in conjunction with isolation of infected animals and disinfection of the premises occupied by them. Diseased animals should be condemned and the use of their milk and flesh as food forbidden. It has been demonstrated beyond peradventure of doubt that the milk of tuberculous cows may contain tubercle-bacilli, whether lesions of the udder or teats be present or not, and such milk may constitute a medium of infection. In order to remove the danger from this source the logical procedure would be thorough sterilization of the milk, but inasmuch as this precaution is, for one reason or another, perhaps more honored in the breach than in the observance, the more practical procedure is to interdict the sale of milk from tuberculous animals. It would, indeed, be a good plan to have the sources of all milk intended for consumption as food carefully and systematically inspected and certificates issued for that derived from non-tuberculous cattle.

Although it was at one time commonly believed that in children the intestinal tract is, by reason of the consumption of infected milk, more commonly than the air-passages, the portal of entry for the tubercle-bacillus, and therefore also the primary seat of the disease, strong evidence has been brought forward to show the fallacy of this belief, although it is probable that the abdominal viscera are rather more commonly the seat of tuberculosis in children than in adults. Under such circumstances the tubercle-bacilli may find their way to the thoracic viscera not alone through the air-passages directly, but also secondarily and indirectly through the pharynx, the tonsils, the œsophagus, and the intestines.

It has been found from a study of post-mortem records that infection with tuberculosis takes place by way of the air-passages rather more than four times as commonly during the first twelve years of life as by way of the alimentary canal, and only somewhat less commonly during the second twelve years of life. Later on, however, the disproportion is much more marked.

It has been pointed out that children may be infected with tuberculosis through the hands soiled as a result of creeping and playing on the floor, and the like. We have here an additional reason, if it were needed, to prohibit indoors, as out-of-doors, indiscriminate expectoration, and to require on the part of the tuberculous patient a strict observance of measures for preventing dissemination of the sputum.

It is a well-known fact that in tuberculous women the menstrual discharge may be replaced more or less regularly by hemorrhage from the lungs. Attention has also been called to the circumstance that in some such patients both the local and the general symptoms are aggravated during the menstrual period. Accordingly, tuberculous women should exercise special precautions at the time of menstruation, being careful to secure more than the customary amount of rest and freedom from excitement and strain.

Hæmoptysis, though an alarming symptom is, as a rule, not a dangerous feature of pulmonary tuberculosis. When it occurs early it is probably a result of hyperæmia in the neighborhood of the local lesion, the blood escaping from the vessels by diapedesis. At a later period it is most likely due to ulceration of the bronchial mucous membrane. At a still later period the hemorrhage is due to rupture of an aneurism or erosion of the coats of an artery in connection with excavation of the lung. Hæmoptysis, finally, may occur at any time in plethoric tuberculous subjects.

As tuberculosis is a communicable disease, notification of the existence of cases should be made to some official body clothed with authority, for the institution of steps looking to the prevention of its spread. The tuberculous patient should be informed

*Read before the Adams County Medical Society, at Gettysburg, August 25, 1904.

as to the communicability of his disease, as to the means of its conveyance, and also as to the measures for reducing the danger of communicating it to others. In case of death or removal, the premises or apartments previously occupied by such a patient should be disinfected.

That there has been a distinct reduction in the morbidity and mortality of tuberculosis should be a source of no little pride to the medical profession, to whose efforts and activities these good results are largely due. This advance must be attributed essentially to a better knowledge of the nature of the disease, its etiology, its mode of dissemination, its prophylaxis, and its treatment.

The differentiation between typhoid fever and tuberculosis is sometimes a matter of no little difficulty, and in this connection it should be borne in mind that the two diseases are sometimes associated. In the latter event, it is probable that the typhoid fever is most commonly intercurrent in the course of the tuberculous affection, or perhaps excites into activity a previously latent tuberculosis, although on the other hand the tuberculosis may no doubt be implanted upon the fever.

In connection with the diagnosis it should be borne in mind that there is at times a close similarity between the symptoms of influenza and those of incipient tuberculosis, or of exacerbations of the tuberculous process.

The prime indication in the treatment of a case of tuberculosis is the improvement of the general nutrition by whatever means possible. This will be met by an abundant supply of fresh air, and good, assimilable, nutritious food, and a proper amount of exercise and rest. Two other requirements are essential in the management, namely, isolation and disinfection. The tuberculous patient is not inherently and essentially a source of danger to others, but he may become so by reason of carelessness in the disposal of his discharges. This danger can be averted by simple measures of disinfection, such as the use of special receptacles for the expectorated matter, keeping the sputum moist, and destroying it by means of heat, or rendering it innocuous by means of chemical disinfectants. In coughing, the patient should hold a handkerchief or a napkin before the mouth to prevent the expectoration blown into spray from being scattered. In so far as these latter measures are enforced the necessity for segregation of the tuberculous patient will be diminished.

It has been learned that it is not always necessary to send tuberculous patients away from home to secure the advantages of climatic treatment. What is needed especially in this connection is a life in the open air, with a maximum of sunshine, and this can, as a rule, be attained at or near home. When possible, the patient should be out of doors all of the time, even during sleep, or, if compelled to remain in the house, windows and doors should be kept open constantly, winter and summer alike. The roof-garden and the tent are useful adjuncts in this connection. With this object in view it has been proposed that camps for tuberculous patients be established on certain forest reservations. A good purpose would be subserved if light agricultural or other form of outdoor work were provided for those able to perform it. This would have a beneficial therapeutic effect, apart from its economic value.

Hydriatic measures have been warmly recommended in the prophylaxis and treatment of tuberculosis. Cold water applied topically is a powerful tonic, improving the appetite, increasing the weight, enriching the blood, augmenting muscular power, stimulating innervation, and accelerating metabolism. It antagonizes retrogressive and favors constructive metamorphosis. By an influence on the peripheral terminations of the sensory nerves and on the vasomotor nerves, it corrects the susceptibility on the part of the tuberculous patient to catarrhal affections of the air-passages. It also exerts a beneficial influence on the local morbid process, inducing increased activity in the flow of blood to and from the affected parts, and improving the circulatory conditions generally. The action of the heart is invigorated, the tone of the vessels is improved, and the entire organism is strengthened. The best plan is to employ a temperature as low as the patient can promptly and completely react from.

It is as yet not possible to speak with assurance concerning the outlook for serum-therapy as applied to tuberculosis. Experimentally results have been obtained that seem to offer the promise of better things, but we have in this connection got scarcely beyond the experimental stage. It may yet be found that uncomplicated tuberculosis is a self-limited disease that, in the absence of secondary infection with streptococci, staphylococci, and other, especially pyrogenic, bacteria, tends toward spontaneous recovery through the development of anti-bodies that exert a destructive influence on the tubercle-bacilli. If this be so, we may hope for the isolation of an antitoxin possessing both prophylactic and curative properties. From the same point of view the necessity for the avoidance of mixed infection, so far as this is possible, is obvious. Good results have been reported from the use of the blood-serum obtained from horses inoculated with progressively increasing amounts of tuberculin until no reaction took place.

Urea has been employed in the treatment of tuberculosis on the basis of the apparently lesser prevalence of the disease in carnivorous than in herbivorous animals. Twenty grains are administered by the mouth three or four times daily, or forty grains hypodermically in four drachms of distilled water. Perhaps the same end is attained by insisting upon the ingestion of a superabundance of proteid food.

Inhalations of formaldehyde have proved useful, compressed air being passed through a 6 per cent. solution. I have had patients saturate with the same solution a sponge placed in a mask held over the patient's nostrils. Encouraging results have been reported also from intravenous injection of formaldehyde—50 c.c. of decinormal salt solution containing 1 part in 2,000 parts.

Rib resection has been practised for the purpose of bringing about collapse of a tuberculous cavity in the lung, and a subsidence of the morbid process. The development of an artificial pneumothorax, with the introduction of nitrogen gas, has been recommended in the treatment of pulmonary tuberculosis, with the object of putting the affected lung at rest. More radical surgeons have even suggested operative removal of diseased portions of lung, provided that the lesion be circumscribed and single. In the presence of abscess or gangrene, surgical intervention would, of course, become necessary.

In conclusion, I desire to reiterate and emphasize

three important parts: (1) Tuberculosis is a transmissible disease; (2) it is a preventable disease; (3) it is a curable disease.

STERILE WATER ANÆSTHESIA IN THE OPERATIVE TREATMENT OF ANO-RECTAL DISEASE;*

WITH A SUMMARY OF THREE HUNDRED AND TWENTY CASES.

By SAMUEL G. GANT, M.D., LL.D.,

NEW YORK,

PROFESSOR OF RECTAL SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It has been in the past, and is at present, the custom of both the general surgeons and the proctologists, with very few exceptions, to insist that patients suffering from rectal diseases, no matter how trivial, must forego business and social engagements and enter the hospital to be operated upon under general anæsthesia. The writer is firmly convinced that this is unnecessary, and indeed unjustifiable in most instances, and for several years he has endeavored to diminish the number of his hospital cases, until during the past two or three years he has succeeded in relieving the vast majority of his patients by radical operation performed under local anæsthesia in the office or dispensary.[1]

The greatest difficulty encountered in the office treatment of these affections was to find a reliable, safe, and effective local anæsthetic. Cocaine and various other agents were extensively employed for some years, but were discarded one after another because of dangerous toxic effects, copious hemorrhage, prolonged postoperative pain, or failure to produce the desired amount of anæsthesia. In employing cocaine solutions it was observed that they were practically inert when distention was not obtained, because of the presence of an ulcer, fissure, or sinus, or because the pushing of the needle through the tissues allowing the escaping of the fluid, although the same solutions were effective where no such opening existed and complete distention occurred; and also that very weak solutions of these drugs were equally as effective as strong solutions when thorough distention was accomplished. From these observations it occurred to the writer that the anæsthetic effect produced by these solutions was not due to the action of the drug, but to the presence exerted by the injected fluid upon the terminal nerve filaments, and experiments were begun in September, 1901, to determine whether sterile water injected into the tissues would produce anæsthesia. It was found that sterile water or decinormal saline solution at any temperature caused effective anæsthesia[2] when the tissues were thoroughly distended. The salt solution did not appear to possess any advantages over the plain water, and the temperature of the water was unimportant in producing anæsthesia, although when warm it caused the least discomfort to the patient.

The cardinal principle in producing pressure anæsthesia by the injection of water is to introduce sufficient water thoroughly to distend the tissues, causing them to become anæmic and assume a glassy whitish appearance, when complete anæsthesia immediately follows. This distention does not require a large amount of water, from ten minims to half a drachm only being necessary for small hemorrhoidal tumors, and from one-half to four drachms in more extensive operations. In introducing the water it is not necessary to use more force than is usually employed in making the ordinary hypodermic injection.

The first distention causes in some cases a momentary stinging pain, and patients should be warned of this, so that they will not jump away and pull out the needle before complete distention is obtained.

The only requirements for producing local anæsthesia by this method are sterile water and a hypodermic syringe, or, better, an aspirating syringe fitted with a fine, sharp needle and a Gant curved extension piece which raises the needle above the body of the syringe so that the latter does not obstruct the operator's view when the injection is being made.

The technic depends upon the nature of the operation to be performed. When a linear incision is to be made through the skin and subcutaneous structures for abscesses, fistula, excision of lipomata, cysts, etc., the removal of clots from thrombotic hemorrhoids, or of foreign bodies from beneath the integument, the procedure is as follows: A fold of the skin at one extremity of the line of incision is caught up between the thumb and forefinger and compressed for a few seconds, which diminishes and often prevents the momentary pain caused by the introduction of a needle. The needle is quickly introduced between the layers of the skin, and a few drops of water are slowly injected, which should produce a small, localized swelling and anæsthesia of the skin at this point. The needle is then introduced slowly further and further along the entire length of the line of the cut to be made, and the water is gradually injected as before, care being taken not to go entirely through the skin. The needle is next plunged deeper into the subcutaneous structures, and they are gradually distended until a linear, firm, whitish, ridge-like swelling is produced. If the procedure has been properly carried out, the skin and underlying structures can now be incised without pain in almost every instance.

The writer has also employed this method to anæsthetize the line of incision for colostomy, abdominal fixation of the sigmoid, and exploratory laparotomy, these operations for obvious reasons being performed in the hospital.

For the thrombotic variety of external hemorrhoids it is necessary to make the injection of sterile water between the layers of the skin only, when the tumor should be quickly transfixed with the curved bistoury, laid open, the clot turned out and cleansed, and the cavity packed with gauze.

In cutaneous hemorrhoids the water must be deposited between the layers of the skin and also into the center of the tumor, after which the tumor can be excised and the wound closed with catgut, or left to heal by granulation.

Large internal, protruding or bleeding, hemorrhoids can be speedily, and, in the vast majority of cases, painlessly, removed by the ligature, clamp

* Read at a meeting of the American Proctologic Society, June 9, 1904.

[1] A plea for the non-hospital or office treatment of diseases of the rectum and anus, Samuel G. Gant, M.D., LL.D., *New York Medical Journal*, April 18, 1903.

[2] For the history of water anæsthesia, see the writer's article, *New York Medical Journal and Philadelphia Medical Journal*, January 23, 1904.

and cautery, or excision after the tumor has been so tightly distended with water injected directly into its center that it turns white. The ligature method is the operation of choice to be performed in the office.

Prolapsus ani, even though extensive, may be cured in the office, and with little discomfort to the patient, by distending with water small or large areas of the mucous membrane and muscular structures of the bowel, which are removed by the ligature or clamp and cautery. Or, on the other hand, linear distention may be done and long segments removed, the wound being left to heal by granulation or closed by sutures.

Ischiorectal, follicular, or marginal abscesses may be opened with but slight pain by injecting the water between the layers of the skin over the abscess, subcutaneous distention being unnecessary. But the writer does not advocate this method of anæsthetization for extensive or deep ischiorectal, circumrectal, or pelvirectal abscesses when much cutting and curetting are essential.

Fissure, ulceration, epithelioma, stricture, and congenital malformations about the anus, constipation, fæcal impaction, or other affections which require operation to increase the lumen of the anal outlet, or which necessitate incision or division of the sphincter muscle, may be operated on under water anæsthesia. For these operations the skin and subcutaneous structures up to the anal margin are distended as previously described, and finally injections are made into the mucosa, submucosa, the external, and, if necessary, the internal sphincter muscle, until a sufficient degree of pressure is exerted upon the nerve endings to overcome sensation. The injection should be made slowly, as rapid distention of this sensitive region may produce considerable discomfort.

The cases in which this method of local anæsthetization has been successfully employed by the writer include radical operations for fissure, ulceration, protruding and non-protruding internal hemorrhoids, cutaneous and thrombotic external hemorrhoids, polypi, prolapsus ani, ordinary complete and blind internal and external fistula, and ischiorectal, marginal, and follicular abscesses; excision of perineal cysts, sacral dermoids, and lipomata of the buttocks; removal of foreign bodies beneath the skin and mucosa; division of the sphincter in constipation, when the muscle was so hypertrophied that divulsion had proved ineffective; fixation of an elongated sigmoid to the anterior abdominal wall; colostomy, and exploratory laparotomy.

This method of anæsthetization is not practicable, however, for excision of the coccyx, or for extensive operations, such as are required for the removal of large tumors by excision or resection of the bowel, or for the relief of the worst types of complete prolapsus recti, complex, horseshoe, rectovesical, rectourethral, and rectovaginal fistula, very extensive abscesses, malformations, or other affections located in the upper rectum. Neither is it applicable for opening the abdomen when there is a thick layer of fat and the tissues are so loose and flabby that a proper degree of distention is impossible.

The anæsthesia and anæmia of the parts occur almost instantly on complete distention of the tissues, and from this it would seem that the effect is produced by the pressure upon the nerves and their endings, or upon the blood-vessels. If the distention is too quickly induced, however, by too rapidly injecting the water, it may cause considerable temporary discomfort, amounting to pain in extremely sensitive persons.

The advantages of water anæsthesia are many:

(1) Effective local anæsthesia is so quickly and easily obtained by this method that in a majority of operations upon the rectum and other parts of the body there is no necessity for the patient to enter a hospital and undergo general anæsthesia. For this reason it appeals strongly to the better class of patients.

(2) The anæsthesia instantly follows the injection of water sufficient to distend tightly the tissues to be incised or removed. This enables the operator to work quickly, and the patient is not confined to the hospital during the after-treatment, but can come to the office to be dressed, thus economizing the surgeon's time and labor.

(3) No annoying or dangerous complications have been observed during or following the injection of the amount of water necessary to produce anæsthesia.

(4) In the writer's experience there has been but little bleeding during the operations, and dangerous secondary hemorrhage has never occurred.

(5) Except for the stinging pain sometimes induced in the beginning of the distention, the patient has but little discomfort during and immediately following the operation.

(6) It eliminates the danger to life from heart, lung, and kidney complications, which are always to be feared during and following the administration of ether or chloroform, and it avoids the increased pain and hemorrhage due to straining and vomiting after general anæsthesia.

(7) The only requirements are a suitable syringe, a needle, and boiled water, and these are usually at hand.

(8) The radical treatment of hemorrhoids and fistula can be so easily carried out under this method in the physician's office, with so little danger and inconvenience to the patient, that it should relegate to oblivion the much-vaunted injection treatment, which is so dangerous and uncertain.

Following operations under this method of anæsthesia the pain is much less than when cocaine and similar drugs are used, as the latter apparently induce a state of nervous excitability in the patient; and, moreover, after their anæsthetic effect has worn off there is increased local irritability of the nerves. There is also less danger of postoperative hemorrhage after this method, due apparently to the fact that the drugs cause a relaxation of the walls of the small vessels, which frequently persists for a considerable time, and permits oozing and sometimes profuse bleeding.

The writer has tabulated 320 cases—243 males and 77 females—operated upon under sterile water anæsthesia in the office or dispensary, giving the details of diagnosis, operation, etc. But owing to the space which would be required to print the complete table, only a brief summary of the table can be submitted at this time.

There were 126 cases of internal, protruding, or bleeding hemorrhoids, 116 of which were operated upon by the ligature, 6 by excision, and 4 by the clamp and cautery method; 44 cases of external

cutaneous hemorrhoids treated by excision, the wound being sutured or left to heal by granulation; 20 of thrombotic hemorrhoids treated by free incision, removal of the clot, and drainage; 16 cases of fissure, 14 requiring complete and 2 partial division of the sphincter muscle; 57 cases of fistula (46 complete, 1 complete internal, 2 complete external, 6 blind internal, and 2 blind external), of which 51 were operated upon by division, 4 by excision, and 2 by ligature; 11 cases of prolapsus recti, 7 operated upon by means of area ligation, 7 by clamp and cautery, and 2 by linear section and suture; 8 cases of ulcer, 2 being excised, 2 incised, 2 curetted, and 2 cauterized; 8 cases of polypi, 6 being removed by the ligature operation, 1 by excision and suture, and 1 by clamp and cautery; 7 cases of abscess (4 ischiorectal, 2 marginal, and 1 follicular) requiring free incision, curettage and drainage; 3 cases of stricture and 1 of congenital malformation of the anus treated by incision; 9 tumors (4 sacral dermoids, 2 lipomata, 2 perineal cysts, 1 epithelioma) treated by excision; 2 cases of foreign bodies removed after incision; 2 cases of constipation and impaction requiring division of the sphincter muscle. In addition there were 3 colostomies for cancer, 1 abdominal fixation of the sigmoid for prolapsus recti, and 1 exploratory laparotomy for suspected intestinal obstruction. These latter operations were performed in the hospital for obvious reasons.

In nearly all these cases the anæsthesia was satisfactory, distention was easily obtained, and the discomfort accompanying it was not great and was relieved immediately by the incision. There was but little bleeding during the operations, and annoying post-operative hemorrhage occurred in only three instances, there being considerable bleeding, which was arrested by external pressure in two of these, while in the third the hemorrhage became alarming, but was finally controlled by inserting a gauze plug into the rectum. In a few instances there was quite severe post-operative pain and sphinteric spasm, for the relief of which the application of hot water to the anus or the insertion of opium and belladonna suppositories was required.

Recently much has been written and said concerning operations performed on other parts of the body under local anæsthesia produced by very weak solutions of cocaine and similar agents, but in the writer's experience the addition of these drugs has been found unnecessary, and although the quantity used may be small, they still possess the disadvantage of sometimes producing toxic symptoms and other complications.*

In conclusion, the writer wishes to state that, while anæsthesia by the injection of sterile water is not effective and cannot be applied in all major operations, he has employed it, to the exclusion of general and local medicinal anæsthetics, in nearly all of his operations upon the rectum (for hemorrhoids, fistula, fissures, etc.), and with such gratifying results that he would heartily recommend its thorough trial by other surgeons for operations in the anorectal and other regions of the body.

* The writer has succeeded in producing local anæsthesia by means of pressure upon the nerve endings induced by compressed air and gases of different kinds, introduced into the skin by means of a porous needle connected with the compressed air tank. The difficulty of retaining the air or gas until anæsthesia was produced was found to be an objection, as was also the danger of air embolism.

43 West Fifty-second Street.

THE ROLE OF THE PROSTATE IN AFFECTIONS OF THE URINARY TRACT.*

By ABR. L. WOLBARST, M.D.
NEW YORK.
ATTENDING GENITO-URINARY SURGEON, BETH ISRAEL HOSPITAL DISPENSARY, CLINICAL ASSISTANT, GENITO-URINARY DEPARTMENT, N. Y. POLYCLINIC AND HOSPITAL.

The purpose of this paper is to consider briefly the prostate as a urinary organ, a point of view suggested by the many pathological conditions of the urinary tract in which we find the prostate involved.

The prostate is commonly spoken of and thought of as a purely procreative organ—an important member of the sexual family of organs. It has been termed the sexual heart, and when we consider its physiological function the name seems certainly deserved. However, a glance at the anatomy of the organ and at its relations to adjoining parts, is sufficient to justify its consideration in its relation to the urinary tract. The urethra, carrying the urine from its reservoir, the bladder, into the outer space, tunnels its way between the two prostatic lobes, its walls, roof, and floor being made of prostatic tissue. This portion of the urethral tract, known as the prostatic urethra or neck of the bladder, is about an inch and a quarter in length, and possesses a decided curve, thus dominating the construction of urethral instruments. The muscular fibers of the prostate completely encircle this portion of the urinary tract, and by their tonic action keep the canal firmly closed.

The so-called "third" lobe, which is in reality not a lobe at all, is a small pyramidal-shaped isthmus of tissue, known as the *pars intermedia* or the posterior commissure, which connects the two lobes below. This mass of tissue is of the greatest importance, for when it becomes hypertrophied, as it often does in old age, to such an extent as to project into the urinary channel, interference with the flow of urine results. It is in this condition that the hypertrophied mass has been denominated the "third" lobe, a term arbitrarily given to a pathological condition. When this outgrowth is present, it may act as a bar at the orifice of the bladder, or it may appear as a spherical mass occluding the neck of the bladder like a ball-and-socket valve. In any event, the obstruction to the urinary flow is well marked, and in extreme conditions may be complete.

Of no less importance in the relation of the prostate to urinary affections is the arrangement of the floor of the prostatic urethra. Anteriorly lies the verumontanum or sinus pocularis, and on either side of it are the prostatic sinuses into which open some fifteen or twenty prostatic ducts. The two openings of the ejaculatory ducts are placed at the anterior portion of the verumontanum. If Nature had purposely aimed to punish those who violate her laws in a manner never to be forgotten, no better plan could have been devised than this arrangement of ducts and sinuses on the floor of the prostatic urethra, leading to the genital organs. In truth the unlawful and blissful moment of joy is too often transformed into days, even years, of despair, through the arrangement just mentioned, for it is by this route that urethral diseases are carried to the deeply seated sexual organs.

In closing this brief and necessarily superficial

*Read at the Third Annual Meeting of the American Urological Association at Atlantic City, N. J., June 9,

survey of the anatomical features of the prostate which have reference to the passage of the urinary stream, mention must be made of the complex nerve supply which brings the prostate into close affiliation with all surrounding parts, and indirectly with organs at a distance. It is this profuse nerve supply that is responsible for so many of the neurasthenic symptoms following inflammation of the organ, the great majority of which are urinary in character.

There is still some diversity of opinion as to the part played by the prostate in the normal urinary act. The opinion expressed by Keyes to the effect that "the prostate has nothing to do with urination, and is quite passive in the act," while it enjoys the support of numerous observers in the past, is quite opposed to the opinion of equally numerous writers, who maintain that the prostate does take part in the act of micturition. It is conceded by all that the primary function of the organ is sexual; nevertheless, these observers agree in attributing to those prostatic fibers lying in intimate relation with the bladder anteriorly, the so-called external sphincter of Henle, a secondary part in the urinary act. In infants, it is well known that the prostatic muscle fibers are practically continuous with those of the bladder walls. In adult age, however, this continuity seems to be modified somewhat by a thickening and reinforcement of the prostatic fibers, which constitute the sphincter of Henle or the neck of the bladder. The preponderance of opinion is well put by Lydston in these words: "While urination might be carried on in the absence of muscular tissue of the prostate, the organ, nevertheless, appears to play a distinct secondary or auxiliary rôle in micturition. While admitting, therefore, that the prostate is to all intents and purposes a procreative organ, it would seem that it is a participant in the function of micturition, and should, therefore, receive consideration as a urinary organ as well."

As has been stated, this paper aims to consider the prostate, as far as brevity will allow, in its rôle as a urinary organ. It is difficult to understand the prevalent tendency that creates a sharply drawn line between the bladder and the prostate in their relation to the urinary function, for the anatomical structure of the relative parts is such as to create a functional and structural continuity between the two organs. The line drawn between the bladder and prostatic urethra is an arbitrary one. It does not exist anatomically, neither is there good reason for believing that it exists physiologically. The prostatic urethra opens into the bladder like a funnel, the wide mouth facing the bladder, the narrow mouth being continuous with the urethra anteriorly. To all intents and purposes the wide mouth of the prostatic urethra is intended by Nature as a continuation of the bladder, and as such it ought to share the honors with the bladder in health, and its misfortunes in disease. Such we find to be the fact in practice as in theory. The bladder cannot perform its normal functions properly if the prostate is diseased; neither can the bladder remain long the seat of disease without affecting the prostate. There is a community of interest, so to speak, that compels a recognition of these two adjoining bodies as common urinary organs. This can well be illustrated by the familiar picture presented by an acute inflammation of the prostatic urethra. The bladder itself is not necessarily involved in the inflammatory process, yet the symptoms are those commonly described as "bladder symptoms." To differentiate between this complex of symptoms and those produced by an acute inflammation of the bladder itself, is by no means an easy matter.

Another interesting point in this connection is brought to view when we compare the normal prostate with the pathological prostate. The normal prostate is essentially a genital organ. At best, its urinary function is a limited one. The importance of the organ in health practically depends on its genital functions. Reverse the picture and study the prostate in disease, and we are confronted with a complex of urinary symptoms. Physiologically a genital organ, the prostate in the pathological condition is at once transformed into a urinary organ. Thus a prostate may functionate properly as a genital organ, and at the same time be responsible for diverse urinary troubles of a character menacing to life itself. Whatever the pathological condition of the prostate may be, sooner or later the predominating symptoms resulting therefrom will be referred to the urinary, and not to the genital, function. This in itself should be a sufficient justification, if one were needed, for the consideration of the prostate as an important factor in urology.

In considering the pathology of the prostate, two conditions stand out preeminently as being the most important, one inflammatory, namely acute and chronic gonorrheal inflammation of the prostatic urethra, the other, the non-inflammatory hypertrophy of the prostate seen in old age. The *bête noire* of the genito-urinary surgeon is gonorrhœa of the prostatic urethra, because of its tendency to chronicity, and the well-nigh impossibility of a satisfactory cure. It has been well said that "were it not for the prostate, gonorrheal urethritis would be a curable disease." Seeking the cause of this condition, we are at once directed to the anatomical structure of the floor of the prostatic urethra, which, as has already been stated, offers the infecting bacteria a nidus from which they can with difficulty, if at all, be removed. In spite of the many material advances that have been made within the past decade, both in our knowledge of the pathological conditions and the remedies with which to attack them, there is a growing number of careful observers who maintain that gonorrheal inflammation of the prostatic urethra cannot be thoroughly cured. Manifestly the task of getting rid of the myriads of bacteria that have invaded this portion of the urinary channel, with its ducts, glands, and sinuses, is not a simple one by any means, as our experience so eloquently can testify. It is not that the germ or its product is less amenable to treatment in this location than in other portions of the body, but it is due to the peculiar structure and situation of the prostate. The gonorrheal inflammation, taking root at the meatus urinarius and traveling backward spares no portion of the canal. In some instances, happily, the disease does not seem to extend to the deep urethra, if we are to judge by the subjective and objective symptoms. Chetwood and others, however, maintain that in every case of gonorrhœa the deep urethra is more or less involved, even though there be an absence of the so-called posterior symptoms. If then, we assume this view to be correct, and granting the difficulty of successfully treating the prostatic urethra once it is attacked, we can readily

see that the prostate is primarily responsible for the chronicity of gonorrheal urethritis.

In this connection it is well to remember that the prostatic urethra leads not only to the bladder, but to the deep genital organs. It presents a division of the roads, so to speak, a bifurcation leading on the one hand to the urinary organs, and on the other to the genital organs. It necessarily follows that any pathological extension from the urinary to the genital tract, or vice versa, must of necessity invade this "thousand-mouthed, succulent prostate," as Keyes puts it.

In acute and chronic gonorrhœa, the rôle of the prostate is a predominating one. In the ultimate analysis chronic gonorrhœa is synonymous with chronic gonorrhœa of the prostatic urethra, while the so-called acute gonorrheal cystitis is in reality an acute gonorrheal inflammation of the prostatic urethra. The acute form may limit itself to the surface of the prostate, or may infect its follicles; it may reach the highest degree of inflammation and lead to abscess formation and suppuration. Between these extremes every degree of inflammation is possible, and the degree of inflammation is reflected and made manifest by the urinary symptoms which follow. Frequent, urgent, and painful urination, and vesical tenesmus, to a greater or less degree, mark the influence of acute prostatic inflammation on the urinary function. In severe cases, the prostate, by its large size, may offer a mechanical obstruction to the flow of urine, becoming more and more marked, and leading possibly to absolute retention. In the majority of instances, the severity of the urinary symptoms is in direct proportion to the extent and degree of prostatic inflammation.

In chronic prostatic inflammation the symptoms are subdued in sympathy with the low character of the inflammation. I know of nothing more exasperating and nerve racking than the neurasthenic patient with chronic prostatitis and urinary symptoms. These symptoms are usually of a reflex character, and may be and usually are out of all proportion to the appreciable pathological conditions. Yet they must be reckoned with, and the responsibility for their occurrence must be laid upon the prostate.

Strange it is that the relations of the prostate to gonorrhœa are so often overlooked. In the literature it is not at all unusual to find the prostatic urethra absolutely ignored. Judging by many of these literary effusions, gonorrhœa and the prostate are strangers, and all that one requires to cure the disease is a two-drachm syringe, a bottle of some astringent or silver preparation and a pus-bag. With this simple paraphernalia, gonorrhœa of the urethral tract lasting for days or months has been reported "cured" in a marvelously short time. In my experience it has been found not only advisable, but imperative, carefully to examine the prostate in every case of gonorrhœa before a patient can be discharged; and it has been found equally essential in every case to examine the condition of the prostate from time to time in the course of the disease. In this way what might have insidiously become a chronic intractable gonorrhœa has time and again been nipped in the bud, as it were, by this precautionary measure.

To sum up the situation, the crux of the matter of chronic gonorrhœa, its pathology and its treatment, lies in the prostate.

Leaving this phase of the subject, we shall consider the prostate in its most important, non-inflammatory rôle—senile hypertrophy. The conditions are self-evident. Without the prostate there can be no prostatic hypertrophy, and without this hypertrophy there can be no consequent obstructive symptoms. The case against the prostate is put in one word—obstruction. For reasons that need not be discussed here, the prostate assumes a pathological enlargement, impinging on the floor of the prostatic urethra or of the bladder at its junction with the latter, thereby narrowing the lumen of the urinary channel to a greater or less degree. Interference with the passage of the urinary stream follows, and the result is a series of urinary symptoms that might be summed up in these words: obstruction, retention, congestion, distention, inflammation, atony, and, eventually, sepsis and death. The condition is essentially a disease of advanced age, though isolated cases have been reported in which it was found in young men between nineteen and thirty-seven years. The statistics vary considerably according to various observers, but it is clear that from 33 to 50 per cent. of all men beyond the age of fifty-five years have enlargement of the prostate, though only about one-fifth of the total number are made aware of the fact by the presence of symptoms. Either the muscular, the glandular, or the connective-tissue elements may predominate, thereby giving character to the growth, and determining the nature and extent of the interference with the urinary stream. Any portion of the organ may be involved. It is well to remember, however, that it is not the extent of the hypertrophy that determines the subjective symptoms, but the manner in which the growth impinges upon the lumen of the prostatic urethra. Thus the hypertrophy may be very great in the direction of the rectum without interfering to the slightest degree with the function of urination; on the other hand, a small teat-like growth pointing directly into the bladder neck may so obstruct the stream as to cause complete retention. Neither does the organ assume a definite shape in its growth. It is apt to be grotesquely enlarged, and irregular in outline, when pointing towards the urethra or bladder, while in the direction of the rectum, its tough fibrous capsule usually determines its growth as a smooth and even mass. Examination of the prostate by rectum is, therefore, not conclusive of the extent or character of the urinary obstruction. A prostate that feels normal to the finger in the rectum may occlude the prostatic channel completely, and vice versa.

The results of prostatic obstruction are familiar, and need no elucidation. Briefly, the bladder wall undergoes a compensatory hypertrophy, which is succeeded by overdistention and thinning of the walls. When this condition has been reached, the ureters and pelves of the kidneys have been involved and have become distended by the back pressure exerted by the urine. The arteries of the bladder walls deteriorate, and the bladder falls an easy prey to germ infection and inflammation from extraneous sources. The urine becomes putrid, its salts are precipitated and agglutinated, and vesical calculus may add its tortures to those that have so long existed. The classic incontinence of retention, with its continued dribbling, is the characteristic urinary symptom of this condition. From this stage to the

condition of general sepsis, the steps are not many, and unless the dam is removed, and the urinary current restored, at least in part, the fate awaiting the unfortunate prostatic is mitigated only by death.

The general practitioner sees these cases in the early stages, and the responsibility for an early diagnosis rests upon him. If he will but bear in mind the axiom that frequent urination in a man over fifty, especially if the urine must be voided at night, incriminates the prostate, he will be able to spare his patients much future suffering. The finger in the rectum, the Thompson searcher in the bladder, the amount of residual urine, and the variations from the normal urinary length, furnish a mass of evidence that in most cases renders the diagnosis certain.

The treatment in theory is simple enough. The obstruction should be removed. Every surgeon has his favorite method, and each method has its advocates. Most likely a careful study of the individual case, and an application of the particular operative methods most suited to the existing conditions, will bring about the best results. In many instances in which the obstruction is not great, the patients can be kept in comfort for a long period by the intelligent administration of the so-called urinary antiseptics.

Chronic contracture of the neck of the bladder is often mistaken for prostatic hypertrophy. Pathologically, the lesion consists of a permanent, unrelaxable, rigid contracture of the muscle fibers encircling the prostatic urethra, constituting a ring-like narrowing of the wide mouth of the prostatic funnel. Fuller compares this contracture to that of the sternocleidomastoid muscle in chronic torticollis; contraction or dilatation is impossible. The mucous membrane lining the bladder neck is congested and thickened, the lumen of the prostatic urethra is narrowed and obstruction to the urinary flow is more or less well marked. The bladder becomes pouched, and cannot fully expel its contents. The residual urine behaves like that of prostatic obstruction, and presents the same symptoms. Diagnosis is made by exclusion. When, in any given case that presents the classical symptoms of urinary obstruction, it is found on examination that the hypertrophy of the prostate, if there be any, is not sufficient to account for the residuum, and there is no increase in the urinary length, we may with reason assume that chronic contracture exists. We may also diagnose this condition when a patient complains of painful and frequent micturition in the course of an obstinate chronic gonorrhœa, without the presence of acute inflammation, and when residual urine can be found without prostatic hypertrophy. At all events, any existing doubts can be expelled by a perineal section.

In neuralgia of the prostatic urethra, we have another manifestation of the influence of the prostate in the causation of urinary symptoms. This condition is more commonly known as Irritable Bladder, and is the result of deep urethral irritability, modified for better or worse, by the general nervous condition of the patient. It is characteristic of these cases that there are rarely nocturnal demands. The urine is clear, though often phosphatic. The neurasthenic element is apt to be strongly developed in these cases, sometimes manifesting itself by adding sexual symptoms to those of the urinary tract.

Prostatic atrophy as the responsible factor in urinary disease is so rare as to be very little understood. It is said that enuresis or retention may mark the range of the symptoms. It is more than likely that it exists often without giving evidence of the fact.

Prostatic tuberculosis is not an unusual urinary condition. The symptoms are those of any chronic inflammation of the prostate. Hæmaturia is sometimes present. The symptoms, of course, depend on the extent and severity of the disease. Objectively, the prostate is found to be enlarged in more or less irregular nodular fashion, with occasional areas of softening. In extreme cases the entire prostate is one cheesy mass, leading to general secondary infection. It is well to remember that tuberculosis of the genital tract cannot extend to the urinary tract without first attacking the prostate. Also, when the inflammatory process extends from one testis to the other, the prostate must likewise be bridged. Here, too, we see the great importance of the prostate.

Calculi of the prostate contribute their share to the subject of urology. They may be considered as vesical stones that have passed from the bladder and lodged in the prostatic urethra, or as prostatic concretions, in which case they consist largely of phosphate of lime and epithelial detritus. Unless they attain a large size and project into the urethral canal, they are not apt to give rise to clinical symptoms. They may work their way forward and come out at the meatus or backward into the bladder, there acting as the nucleus of a larger vesical stone. Here we see how the prostate may be responsible for vesical calculus.

Malignant disease of the organ will also give rise to urinary symptoms of a severe character. Primary malignancy with extension to the bladder is not unusual, though the reverse is quite rare. In children the type is that of sarcoma, ten per cent. of all reported cases having been sarcomata in children under ten years of age. The clinical signs are those of mechanical obstruction followed by those of nerve pressure and extension to adjacent parts. The symptoms are extremely painful, and dissolution occurs within one year after the onset of the disease. Reflex sciatica, especially when bilateral, is said to be indicative of prostatic cancer.

When the prostate is injured by blows or kicks, urinary symptoms will result, the severity depending upon the character of the wound or injury. Internal hemorrhage is very likely to follow if the rich prostatic plexus of veins is injured. Urinary infiltration is also a possible result. The blood may flow backwards into the bladder, forming a hard, coagulated mass, which may be extremely difficult to remove. Prostatic cysts may interfere with the urinary stream if they are large enough to occlude the urethral canal. It should also be remembered that the prostate may be indirectly responsible for suppuration and other important lesions in the kidneys.

Conclusions.—The prostate, though a sexual organ in health, is essentially a urinary organ in the diseased state.

Urinary symptoms are most often directly due to prostatic disease.

Any pathological lesion of the prostate which increases its size favors interference with the urinary stream to a greater or less degree.

Inflammation of the prostate is always accompanied by urinary symptoms. The genital symptoms are least marked.

In reference to gonorrhœa, the prostatic urethra is the most important portion of the urinary tract; it is the favorite seat of chronic urethritis; it is the medium over which the inflammation travels from the urinary to the genital tract.

The prostate is solely responsible for the important urinary conditions which result as a consequence of its senile hypertrophy.

Prostatic concretions may lodge in the bladder and act as the nucleus of larger vesical calculi.

Chronic contracture of the bladder neck, neuralgia of the prostatic urethra, prostatic tuberculosis, malignant prostatic disease, prostatic cysts, and trauma of the organ, are all made evident by their effect on the urinary function.

Lastly, these numerous urinary affections justify the consideration of the prostate as a urinary organ, second only to the kidneys in importance.

MUSIC AS A THERAPEUTIC AGENT.*

By FRANCIS S. KENNEDY, M.D.,
BROOKLYN, N. Y.

It is not my intention to, nor does time permit that I should, go into the subject of "Music as a Therapeutic Agent," with the object of dissecting musical composition, nor of demonstrating the niceties of counter-point, fugue, and harmony, but rather to take music as we find it, and to see wherein it meets the requirements of the physician in treating certain classes of patients.

From the great array of drugs, we select such remedies as we know will prove of service in meeting a given class of symptoms; not alone is the proper drug selected, but careful direction is given as to its preparation and the method of administration. The physician who would go into the sick room and say: "This patient requires drugs; send out and get a quantity, then administer freely," would be a fit subject for treatment himself. Fortunately for our purpose, music is not a new thing, but has been in existence since the beginning of time; while its variety, color, strength, source, and application are as great as the drugs of the pharmacopœia.

Musicians and composers have rivaled the chemists and pharmacists in the making of new combinations and the producing of new effects. The one produces symphonies, operas, and folk-songs; the other provides tinctures, fluid extracts, and powders; yet the therapeutist can find in both groups the tonic, the stimulant, the sedative, and the narcotic.

The chemist announces the discovery of a new drug and offers it for consideration and trial. He finds that five grains have killed a dog, while two grains have produced sleep in a guinea pig. It is therefore suggested that initial doses should not exceed a quarter of a grain, and that it could be tried in cases of insomnia, a close watch being kept on the heart action. The musician announces a new slumber song, quiet, soothing, without danger to life, and capable of producing restful sleep. His production was not the result of an accident, for before a single note or chord was written, he knew what effect he desired to produce on the listener, and his whole endeavor was to that end.

Music has an unquestioned and positive action on the mind and body which cannot be doubted. Dogiel finds, in his "Experiments Upon Men and Animals," that music, according to its nature, will either increase or decrease blood pressure, the extent being governed by the character of the music and the personal susceptibility of the individual. He also finds that the pulse rate is retarded or accelerated under the same conditions, and that the respiratory rhythm is modified in direct proportion to the pulse-rate. Dr. Herbert Lilly, in his pamphlet on the "Therapeutics of Music," argues that musical sounds being received by the auditory nerve produce reflex action upon the sympathetic system, stimulating or depressing the vasomotor nerves and thus influencing the nutrition of the body.

By what channels and by what processes the sympathetic system and the emotions are affected when musical harmonies reach the ear mechanism, does not concern us at this time; these points were elaborately considered some five years ago by Dr. J. Leonard Corning, of New York, and his conclusions published at that time in the Medical Record. The fact remains, however, that certain mental conditions are benefited by suitable musical harmonies, that muscle fatigue is overcome or forgotten by the production of stimulating music, and that even the complex process of digestion is benefited by appropriate music—the kind which the French call "liver music," and furnished by them at banquets.

The whole purpose of music is to produce impressions, and thereby affect the emotions. So true is this in its workings that the same effect is produced on the child and upon the adult of education; upon the white man and upon the savage; upon the human being and upon the lower animals. The soldier upon the march forgets his weary muscles as the band sounds an enlivening piece of music of fixed measure. His head is held a little higher, his back becomes a little straighter, while the length of his step is increased an inch or so and is more elastic. The running athlete is lifted over the ground in better time when aided by a brisk quick-step, for he feels the inspiration in every muscle. No one could dance to either a slumber song or a nocturne, nor would an infant pass over into dreamland in the presence of a brisk march or waltz.

Back in the early years of this country, when the Moravian settlement at Bethlehem, Penn., was but an infant in years, when the surrounding country was a wilderness, with hostile Indians at every hand, a sentinel from the settlement rested wearily upon the hillside, which sloped toward the river below. His eyes were to the front, watching for the first signs of an expected Indian attack; his heart and thoughts were back in his little crude home, where a loved one was dangerously near the great divide. Slowly an Indian crossed the river and noiselessly began to climb the hillside toward the settlement. He was the first of a long, sinuous line. His alert watchfulness soon discovered the white settler. His arrow was ready, his bow drawn, but a second more and a swift, silent messenger of death would have flown to its mark. Suddenly, through the soft evening air, from the heights above, came the full, clear tones of a trombone choir, in solemn, dirge-like

*Read before the Section on Medicine, of the Medical Society of the County of Kings (N. Y.), May 23, 1904.

splendor, announcing the death of one of the settlers.* Slowly the arrow was lowered, slowly the bow-string was relaxed, softly the Indian warrior retraced his steps, saying to his followers: "The Great Spirit speaks in soft sounds and without anger. The Great Spirit says Peace." The settler knew by the tones of the anthem that the loved one had passed away, and with bowed head he murmured: "Thy will be done." The music which told the white man of sorrow brought a spirit of forgiveness to the savage.

Music always reaches that sub-conscious part of our mysterious mechanism; it affects the subjective mind, swaying it one way or another, and leading it unconsciously, as if by inspiration, in whatever channel of thought the character of the music compels. Nearly every one is peculiarly susceptible, often unconsciously so, to some special piece or class of music which appeals to him under certain circumstances; he may also have an equal degree of intolerance for other kinds.

Just as we avoid quinine with one patient and iron with another, while in some other cases the minimum dose will act like a charm, so it is with music. The rag-time or even a bit of opera would be unattractive or repulsive to some, while a rich melody from the south or an old familiar home song would prove interesting at once, and restful.

To consider in detail the particular kind or class of music which would be specially suited to each of the many kinds of cases would not be possible in the limited time at our disposal, for its field of action reaches into all departments of medicine, including surgery and dentistry.

Do not imagine for a moment that I wish to convey the idea that a Chopin nocturne would amputate a leg, but it would, as a post-operative measure, have an undoubted influence for good in taking the patient's mind from his bodily distress. So, also, could "painless" dentistry be relieved of some of its pain and distress by the quieting influence of music, which would, as has been amply demonstrated, produce a pleasanter mental influence during the administration of nitrous oxide or other anæsthetic.

A German writer has recently stated (February, 1904) that in a number of test cases in which music was provided during the administration of the anæsthetic, there was an absence of distress and resistance on the part of the patient; also an absence or reduction of the post-operative nausea under the same circumstances.

Melancholia, insomnia, hysteria, family affliction, business reverses, delirium, pain, fatigue (mental or physical), will all be helped by the beneficial influence of music, rightly used. The general practitioner advises hydrotherapy, electrotherapy, heat, cold, light, and darkness, because they have a marked influence upon the body and mind. The threat of cold water in hysteria has a mental influence, and the tired physician himself goes to a concert for rest.

Music, like any other remedy, to be of service as medicine, must be suited to the particular needs of the individual, free from antagonizing elements, and administered in such a manner as to produce benefit.

Music will not do everything, nor will it always be tolerated by the patient—neither will drugs, surgery, or the electric current.

The problem presenting itself to the physician, therefore, is not as to the supply, quality, or efficiency of music as a remedy, but purely as to the selection of the proper kind and its administration. The majority of medical men and women know more about music than they do of electricity, and more of surgery than of either; yet the surgeon and the electrotherapeutist, both as consultants and specialists are recognized as a necessity. We have medical men who are musicians, and many able musicians who would be valuable consultants as to theme and method of administration. These factors would differ, to a degree, with every patient. The organ, the violin, the 'cello, and the harp are all available as means of producing proper music, but in each instance the execution must be smooth, expressive, and free from error. The piano is found in the majority of homes and institutions, and is always available.

There can be but little doubt that many of our trained nurses would be found capable performers upon the piano, and also to possess voices of suitable quality; if so, they could make themselves of double value. The quality of voice and the ability to sing or play should be judged, however, by some one other than the owner or performer.

In this connection, it may be of interest to note the work which the St. Cecilia Guild of London is endeavoring to do, according to their prospectus:

They desire (1) to institute a series of investigations to determine the extent of influence which music has upon the heart, blood-pressure and respiration. (2) To train a corps of special musicians, both vocal and instrumental, who would be expected to respond at any hour of the day or night to the calls of physicians or institutions, and who would be particularly competent to either sing or play such style of music as might be required. (3) To establish in some central hall or building a continuous performance of music, this to be transmitted by telephone direct to the bedside or room of the patient whenever required.

NOTE.—Following the reading of the paper, two methods of administration were demonstrated, one by the piano and the other by the voice, and an endeavor made by each method to illustrate the different impressions which could be conveyed to the listener. Just as a drug should be put up in a clean package and as free from adulteration as possible, so music as a medicine should be as free from error of technique as possible. For this reason, in demonstrating the piano music, a mechanical piano-player was used so that no false tone should mar the harmony and effect. The following examples were then rendered: As restful music yet sufficiently stimulating to keep the mind alert, "The Fifth Nocturne," Leybach, piano. As soothing, quieting music, "An Irish Lullaby," Needham, contralto. As physically stimulating music, "The Invitation to the Dance," von Weber, piano. As mentally stimulating music, "One Spring Morning" (Goethe), Nevin, contralto. As reminiscent, memory-refreshing music, "Fantasie from Il Trovatore," Sydney Smith, piano.

462 GREENE AVENUE.

*It is an old-established custom at Bethlehem that when a death occurs in the Moravian congregation, the fact is announced by the trombone choir from the church belfry, the character of the anthem designating the class and condition of the deceased—whether old, young, male, female, married, or single. This custom is said to have prevented a massacre, as above noted.

Opium Smoking is not as purely Oriental a vice as is usually supposed, for it is estimated that there are 1,000,000 devotees of the pipe in the United States.

Cheap Goggles for automobilists are said to be very injurious. They should be fitted to the eye by an optician to ensure their being properly placed in regard to the visual axis.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, October 29, 1904.

THE PASSAIC VALLEY SEWER.

THE recent decision of the Supreme Court of New Jersey, affirming the constitutionality of the law authorizing a sewerage system for the cities of the Passaic valley, to discharge into the waters of New York bay, has excited a good deal of adverse comment among many citizens of New York, who regard this proposed method of sewage disposal as directly prejudicial to their interests and health. It is expected that the sewer which will be about twenty-four miles long, will cost some $9,000,000, and will discharge daily about three and a quarter millions of gallons of sewage, from Paterson, Newark, Passaic, and other towns, into New York waters.

As the details of construction of the proposed sewer, and methods of sewage disposal, have not yet been announced, it cannot be stated whether or not this opposition to the proposed plan is justifiable. New York already pollutes with its filth to too great a degree the waters adjacent to it, especially in view of the proposed use of salt water for fire purposes and street sprinkling. Naturally, any plan further to contaminate these waters with crude sewage, which, vast in its proposed amount, would be certain steadily to increase in quantity with the rapid growth of population in the New Jersey cities mentioned, would be viewed with justifiable alarm, and should be contested in the courts. On the other hand, if comprehensive and, necessarily, somewhat costly measures for the purification of this sewage by the septic tank system are taken, and the sewage is thus purified before discharge into New York waters, the effluent would probably be purer and less dangerous to health than the present water flowing in the Passaic river itself. Although the septic tank system of sewage purification is a relatively new thing, its efficiency is already so conclusively established that the time has arrived when the law should forbid one community from disposing of its sewage in the vicinity of another community without such purification. Even in the present state of development of the septic tank system, it is possible to destroy all the offensive qualities of sewage, and discharge an effluent without color, odor, or suspended matter, and from which more than 98 per cent. of bacteria have been removed. In the case of the proposed sewer, it is perfectly possible, by the expenditure of sufficient money, to render the effluent inoffensive and harmless, and the State of New York should promptly take any steps which may be necessary to force the New Jersey authorities, in putting in their sewer, properly to safeguard the interests and health of those who might otherwise be affected thereby. If modern scientific methods of purification are used, the municipal liquid wastes can be so deprived of the gross and microscopical characteristics of sewage as to require little more attention in the matter of their ultimate disposal than would be needed in respect to the disposal of storm water. For any community to take advantage of its geographical situation to flood a less fortunate neighbor with hurtful sewage wastes is indefensible in equity, and happily quite unnecessary in modern sanitary practice.

The Health Officer of New York is quoted as advising that the New Jersey cities in question chemically purify and dispose of their own sewage at home, and as stating that the sewage of New York itself should be "chemically treated and rendered harmless." The chemical purification of sewage is a relic of a past generation, and it is doubted if it has been satisfactory, from either a sanitary or economic standpoint, by any process, in a single instance in which it has been used. Certainly the congestion in New York would render any attempt at local sewage purification by chemical means, from the nuisances unavoidably attached to purification plants of this kind, absolutely impossible. It is practicable, however, to attach septic tank fixtures to many of the existing sewers, and certainly no new sewers should be built without such provision. By this means, additional gross pollution of the waters adjacent to New York can be prevented, and their present pollution can be considerably reduced in degree. If those who favor the chemical treatment will consult any good sanitary engineer, they will find that the chief problems relating to the prevention of the pollution of New York waters are solvable by far simpler and more economical and effective measures.

THE NATURE OF CARCINOMA.

IN spite of the efforts that are being expended by observers all over the world, who now have at their command the data available from hundreds of experiments and thousands of observations, the knowledge we have obtained concerning the true inwardness of malignant growths has not progressed at all in proportion to the advance that has been made in other branches of pathological investigation.

The list of believers in the nonparasitic nature of carcinoma is large, and includes many illustrious names, such as those of Waldeyer, Colnheim, v. Hansemann, Ribbert, and Lubarsch, but embryonal inclusion, traumatic displacement, anaplasia, whatever may be the scientific catchwords which investigators apply to their theories, are all the merest surmises, and have found but little clinical corroboration. At present, belief in the parasitic origin of carcinoma is perhaps more in vogue, and the number of alleged cancer parasites is to be counted almost by scores. Three forms of microbic life have to bear the stigma of the alleged etiology of this scourge, and members of the protozoa, the bacteria, and the yeasts or blastomycetæ have all been saddled with accusation by enthusiastic observers. While it is true that many of these riders of pathological hobbies have come to grief, and later investigation has shown that their elaborately described and figured parasites were only foreign contaminations,

such as cork cells, or various irrelevant cell inclusions or artefacts, it must be admitted that the blastomycetic theory has much in its favor. It is still, however, far from being proved, and it is quite possible that the substance of carcinomatous growths, which Freund, in 1889, showed contained from twenty to thirty times more carbohydrate than normal tissue, may afford a more suitable culture medium for the growth of yeasts than of bacteria, and that the predominence of blastomycetic forms is in this way accounted for. The lines between the widely disseminated non-pathogenic and the so-called specific forms of these organisms are also not clearly drawn, and much systematic work is yet needed before some of the results obtained can be interpreted.

Lubarsch has expressed his skepticism of the parasitic theory very strongly, and says that so far no one has succeeded in proving that any microorganism is the specific cause of carcinoma, or of any other independent new growth. No analogous cases have been found in plant or animal life which would explain a parasitic origin, and neither the statistics, the results of experimental work, nor the clinical observations, bear out the parasitic theory of cancer.

Serkowski and Maybaum (*Deutsche Medizinal-Zeitung*, September 12, 1904), in a résumé of our present knowledge in regard to the question, conclude that we know just about as little concerning the nature of carcinoma as did Hippocrates, and that the parasitic theory cannot be said to be either proven or disproven. Many things, however, speak in favor of the infectious nature of the disease, such as the infection of medical men at operations and autopsies, the clinical course of the disease, and the very numerous instances now recorded of *cancer à deux*, occurring in husband and wife, or in people brought into close personal contact with each other, such as nurses and patients, room-mates, etc. These authors conclude that more attention should be paid to prophylaxis, and that, in view of the possible parasitic nature of the affection, the secretions of carcinomatous patients should be treated with the same precautions as those of tuberculosis and syphilis. The hands should be disinfected after all operations, dressings, vaginal and gastric irrigations, etc. Clothing, linen, instruments, and sick-room articles used in the care of carcinomatous patients should not be employed again without thorough disinfection. A more careful control should be exercised over water supplies, drainage and sewerage, and the preservation of food, particularly against contamination by insects. In other words, these patients should be treated as are those suffering from any infectious disease, and the same precautions should be taken to prevent direct or indirect transference of the malady.

The Ehrlich Diazo-Reaction.

When Ehrlich, in 1882, described his diazo-reaction in the urine, the medical world received with great interest what promised to be one of the most useful diagnostic signs of that elusive malady in the name of which so many diagnostic crimes had been committed—typhoid fever. But as clinical and experimental data increased, as the years rolled on, the diazo-reaction came to be looked upon as one of those laboratory methods which cannot walk unsupported by the substantial crutches of clinical symptoms, until finally to-day the reaction is known to occur in such a variety of conditions and in such a multitude of circumstances that its diagnostic value has dwindled considerably.

In the present state of our knowledge concerning Ehrlich's test we have by no means reached a thorough insight into the exact way in which it takes place, and especially into the various factors, normal and abnormal in origin, which influence the intensity of the brilliant color obtained in the typical reaction, as described by the original observer.

A recent study on this subject by Campanella, of Catania (*Gazzetta degli Ospedali e delle Cliniche*, July 10, 1904), is of interest, because it concerns itself particularly with the modifications in the diazo-reaction wrought by such commonly-used drugs as salol, and such constant elements of the urine, as urochrome and indican. This author found that in healthy persons, who had been taking salol, the reaction appeared clearly in the urine within a few hours, and that urochrome, indican, and diacetic acid, each separately, when present in excess, intensified the diazo-reaction to a marked degree.

As regards the influence of drugs upon the diazo-reaction, Campanella's experiments show nothing very strikingly new. The fact that some drugs induce the appearance of Ehrlich's reaction in a urine in which it has previously been absent, is well known. Zung has mentioned codeine, resorcin, the salts of quinine, digitalin, and creosote. Chrysarobin and naphthalin are apt to cause the appearance of the diazo-reaction, but the reaction resulting from the ingestion of these drugs differs from the true diazo-reaction by the absence of a green precipitate, which occurs in the latter on standing for twenty-four hours. This differential point has been noted by a number of observers, but Campanella makes no mention of it as a means of distinguishing the true from the false diazo-reaction. On the other hand, other drugs, such as tannin and preparations containing it, such as cinchona bark, rhatany, etc., as well as the iodides and iodine itself, inhibit the development of Ehrlich's reaction, according to Burghardt and others.

The researches of Campanella, which deal with urochrome, indican, and diacetic acid, and with the influence of these upon the diazo-reaction are especially noteworthy. The fact that variations in the amounts of these constituents of urine run parallel with modifications in the intensity of the diazo-reaction possibly accounts for the mysterious irregularity with which Ehrlich's phenomenon appears in some patients. If it is true, as Campanella believes, that these substances, when present in excess, can cause the appearance of Ehrlich's reaction, then this test can scarcely serve even as a relative diagnostic sign of typhoid fever, and our notions concerning its significance in disease in general must undergo revision.

Health of Americans in the Philippines.

First Lieutenant Wallace De Witt, Assistant Surgeon, U. S. Army, writes in the *Yale Medical Journal* for August, 1904, on the above subject. He deprecates the exaggerated statements so frequently made, that a tropical climate in itself has a most deleterious effect on the health of the white man. He concedes the fact that an American cannot work in the tropics with the same energy as in temperate climes, but insists that, using proper precautions, an individual may keep in excellent health. The great drawback, from a hygienic point of view, in the Philippines, is the bad sanitary conditions existing therein, greatly aggravated by the un-

cleanly habits, superstition, and ignorance of the native and Chinese population.

Diseases of the skin are remarkably prevalent in the Philippines, and lucky indeed is the American who does not contract one or other of the numerous parasitic skin diseases which are the bane of the islands. Gastrointestinal disorders occur with great frequency among the American dwellers in the Philippines, and according to the author, the treatment of the two most severe forms—dysentery and sprue—has been unsatisfactory.

Among the infectious diseases, cholera is most to be dreaded, while another highly infectious disease is dengue. Pulmonary tuberculosis is also extremely frequent among the native population, and is a source of danger to American residents.

Concerning the most suitable form of diet for white men in the Philippines, Dr. De Witt expresses himself in favor of a similar dietary to that which the American is accustomed to in his own country. Great care, however, must be taken to provide pure food and water. Another important point is to insist that clothes and linen are thoroughly washed in hot water, in order to guard against infection by parasitic skin diseases. Stringent precautions must also be taken against mosquitos.

The author states, with respect to clothing, that it is sufficient if it be cool. He is of the opinion that the wearing of an abdominal flannel belt is contraindicated, as experience has shown that wearers of this kind of band fall victims as readily to intestinal disorders as those who have never used them; besides which the belt is hot and uncomfortable, and unless changed frequently is always damp from the absorbed perspiration.

Dr. De Witt concludes that while the Philippine Islands are by no means what may be called a healthful country, yet by the exercise of a few necessary precautions, the average American can live there for an indefinite period and enjoy good health.

Intra-Articular Injection of Sodium Salicylate in Multiple Arthritis.

At the Egyptian Medical Congress, held in December, 1902, Bouchard presented a communication in which he advocated treatment of syphilitic and other affections by the local rather than the general administration of the so-called specific remedies. Prompted by this suggestion, A. Santini employed periarticular injections of sodium salicylate in a number of cases of polyarthritis with variable results, sometimes entirely negative. Thinking that this was due to the fact that an insufficient quantity of the drug entered the joint itself, he injected the salicylates directly into the articulation (*Weiner klinisch-therapeutische Wochenschrift,* September 4, 1904), and thereby obtained very good results, rarely finding it necessary to treat a joint more than once. The most efficient solution is one of three per cent. strength in sterile water, this being isotonic with the blood. In most joints a spot will be found where the capsule is slightly distended and here the fluid can be injected. At the shoulder, however, the injections can only be made close to the joint. The dose varies with the size of the joint, but Santini says that from 3 to 5 c.c. of the solution is usually sufficient. When the joint is very much distended, some of the fluid may be aspirated before the remedy is injected. The pain becomes immediately worse, but soon subsides, and the temperature drops. The individual joints may be injected on successive days, and in the four cases reported a cure was secured by the use of from 24 to 60 cgm. of the salt.

Hyoscine Poisoning.

Dr. J. C. Given (*Liverpool Medico-Chirurgical Journal,* June, 1904) has recently reported a case of this form of poisoning. A patient of the physician in question, aged sixty-nine years, was ordered by him hyoscine hydrobromate gr. $^1/_{200}$ in one drachm of water, to be taken at bed time. The pharmacist to whom the prescription was taken read gramme for grain, with the consequence that the patient took fifteen times more than he was intended to take. About half an hour after this dose had been given the patient was deeply comatose, and Dr. Given was called in. Strychnine was injected and brandy given by the rectum, with no beneficial results. Morphine and caffeine were administered hypodermically with little or no improvement. Then the stomach was washed out by the syphon tube with hot water, and about eight ounces of strong black coffee was passed into the stomach. In an hour improvement was shown, which gradually continued until eleven hours after taking the dose consciousness returned, and recovery was uneventful.

Dr. Given makes the occurrence a plea for the adoption of the metric system in Great Britain, arguing, rightly enough, that the present condition of the weights and measures in the British Pharmacopœia, by which it is now optional whether the decimal system or apothecaries' weight be used, is a source of constant danger. With regard to antidotes to hyoscine poisoning, besides those given in the case mentioned, pilocarpine is frequently used. Dr. Given thinks that the recovery of his patient was largely due to caffeine, administered both as such hypodermically and as strong coffee.

Smallpox in Children.

Of 111 children under ten years of age removed to the Isolation Hospital in Chicago last year, 105 were under and only six were over school age; eighteen were under one year old, thirteen between one and two, twenty-two between two and three years. Up to October 1 of this year there have been sixty-two cases in children less than ten years old, of which number fifty-seven were under and five over school age. Dr. J. D. Rawlings, Assistant Chief Medical Inspector, in charge of the Isolation Hospital, in commenting on these figures, refutes the popular fallacy that the infant in arms is not susceptible to smallpox, and he also shows the great practical value of the vaccination requirements for school attendants. As Dr. Rawlings says, it is the duty of physicians to educate the population, so that parents will have their children protected against smallpox from infancy, instead of advising delay in vaccination until the school age is reached, as is now too often the case.

News of the Week.

A Paper by Sir Felix Semon.—The regular meeting of the section on Laryngology and Rhinology, of the New York Academy of Medicine, for October 26, is postponed until November 2, at 8.15 p.m., in Hosack Hall, when Sir Felix Semon, of London, will read the paper of the evening: "Malignant Tumors of the Larynx." It will be discussed by Drs. Hartley, Brewer, Gerster, Delavan, Bodine, Bosworth, B. F. Curtis, and Wright.

Columbia's Anniversary.—The one hundred and fiftieth anniversary of the founding of King's College will be celebrated by the trustees of Columbia University on Friday, Saturday, Sunday, and Monday, October 28 to 31. A reception will be held in the Low Memorial Library and the various buildings

of the university will be open for the inspection of the alumni and their friends. The professors and other officers will be in their departments to explain any details in regard to the equipment and administration of their work.

Dr. Knopf Receives a Prize at the St. Louis Fair.—The Superior Jury of Awards of the Louisiana Purchase Exposition has awarded to Dr. S. A. Knopf, of this city, a gold medal for his work on tuberculosis. The exhibit consisted of Dr. Knopf's English, French, and German textbooks on tuberculosis; his contribution on tuberculosis in the Twentieth Century Practice of Medicine, his various addresses and lectures, and his International Prize Essay, "Tuberculosis as a Disease of the Masses and How to Combat It," with translations in eighteen languages.

Dr. Samuel W. Lambert Appointed Dean of the Columbia Medical Department.—The Deanship of the College of Physicians and Surgeons of Columbia University, which has been filled by Dr. John G. Curtis, as Acting Dean, since the resignation of Dr. McLane, in June, 1903, has been filled by the election, for the statutory term, of Dr. Samuel W. Lambert, Professor of Applied Therapeutics. Dr. Lambert becomes *ex officio a member* of the Columbia University Council, of the Board of Trustees of the Roosevelt Hospital, and of the Boards of Managers of the Sloane Maternity Hospital and of the Vanderbilt Clinic. Dr. Lambert is a graduate of the College of Physicians and Surgeons in the class of 1885.

Officers of the County Medical Society.—At the ninety-ninth annual meeting of the Medical Society of the County of New York, held October 24, the following officers were elected: *President,* Dr. Henry S. Stearns; *Vice-Presidents,* Drs. Floyd M. Crandall and Walter L. Carr; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. Edmund P. Fowler; *Treasurer,* Dr. Charles H. Richardson; *Censors,* Drs. Wendell C. Phillips, H. S. Houghton, W. H. Park, Joseph Brettauer, and Egbert Le Fevre.

Accident in the Jersey City Hospital.—The ceiling fell in the drug room of the Jersey City Hospital a few nights ago, and wrecked the stock of medicine and nearly caused a panic among the patients. The building has been in a bad condition for a long time, and the erection of a new building has been under consideration for many months. A bill was passed by the Legislature, under which commissioners were appointed. The Mayor and board became involved, however, in a dispute over the plans, and when the board awarded the contract its action was not concurred in by the Finance Board.

Illegal Use of a Surgeon's Name.—On the complaint of Dr. John B. Murphy, of Chicago, Dr. N. News Wood, president of the so-called Christian Hospital, was recently arrested and taken before Judge Holdom. He was released on $1,000 bonds, furnished by his wife. Dr. Wood was accused of violating an injunction granted in July, 1903, restraining him from using the name, signature, or picture of Dr. Murphy in connection with the Christian Hospital, or from representing that Dr. Murphy has or ever had any connection with the establishment. Former Judge George W. Brown, acting for Dr. Murphy, charged that Dr. Wood had been selling membership certificates bearing Dr. Murphy's portrait, and also was using the surgeon's name illegally.

Agassiz Scientific Cruise.—Under the direction of Prof. Agassiz, of Harvard, an expedition on the Government steamer *Albatross* will cruise for several months in the Pacific, in the region of the Galapagos Islands, Callao, and the Easter Islands, engaged in deep-sea sounding work and in studying the pelagic life of that quarter. The *Albatross* will have on board with Prof. Agassiz, Prof. Kofoid, of the University of California, an artist, and a Harvard assistant, and two assistants furnished by the United States Fish Commission. It has already sailed from San Francisco, leaving there three weeks ago to meet the Harvard party at Panama. Most of the expenses of the expedition will be borne by Prof. Agassiz himself.

Teachers for Tuberculous Children.—At a recent meeting of the executive committee of the Board of Education, a request was received to assign teachers to thirty-six children suffering from tuberculosis. The children are in the Seaside Tent Camp at Coney Island, where they are being cared for by the Association for Improving the Condition of the Poor. The society offered to supply a schoolroom if the Board of Education would furnish the desks, books, and teacher. It was decided to comply with the request.

Care of the Insane in Illinois.—Legislation will be sought soon transferring the Dunning (Ill.) Hospital for the Insane from County to State management. The plan provides for a division of the institution. It was proposed to transform Dunning entirely into a State Insane Asylum, and establish the Home for the Poor and the Hospital for Consumptives on some large tract of land farther from the city of Chicago. The County Board approved the proposition and referred it to the Committee on State Legislation. This committee will petition the State Board of Public Charities to recommend to the General Assembly at the approaching session the enactment of the necessary legislation for the transfer.

Summary Disposal of the Undesirable.—At the annual meeting of the National Prison Association, held last week, Dr. Henry Hatch, of Quincy, Ill., read a paper advocating some very radical measures in respect to the mentally, morally, or physically diseased. He is reported to have advocated granting permission for, or encouraging, suicide by those suffering from an incurable disease, and to have urged that the State dispose of the incurably insane by putting them to an easy death. He advocated also the prevention of marriages of undesirable persons, the restriction of saloon-keepers from selling liquor to habitual drunkards, and the castration of all persons convicted of sexual crimes. The speaker's views met with little support from his hearers.

The Staff of the Cook County Hospital, Chicago.—The Cook County (Ill.) Commissioners recently adopted a resolution reducing the attending medical staff at the County Hospital to 65 members, and providing a merit test for appointment. It was thought by the President of the County Board that the attending staff at the County Hospital had grown so large as to impair its efficiency, and work a hardship on the doctors who stood ready to render their best services to the county. Hereafter a competitive examination will be conducted by a competent examining board, under the direction of the Civil Service Commission, and in accordance with the provisions of the Civil Service law.

Dr. H. L. Woodward has been appointed clinician to the children's clinic of the Medical College of Ohio.

New Free Bath for New York.—Plans have been filed with the Superintendent of Buildings for a public bath house, for which the city will pay $250,000. The new building will be located in Avenue A, between Twenty-third and Twenty-fourth streets. It will be surrounded by a garden, having

a frontage of 163½ feet and a depth of 140 feet. The construction will be of ornamental brick, with trimmings of limestone, granite, and terra cotta. There will be a decorative cornice, surmounted by a flagstaff. Two main entrances will be arched and decorated with ornamental glass, with broad staircases of granite. The interior will have an arched roof and the flooring will be of tile. The natatorium pool for men will be 25 feet by 60 feet, and that for women 25 feet by 40 feet. This pavilion will be open winter and summer.

The Work of the New York State Lunacy Commission.—An abstract of the reports of the Lunacy Commission for the last three years has been made by Drs. George B. Fowler, Edward D. Fisher, and Carlos F. MacDonald, showing the progress in the care of the insane in New York State made during this period. The Commission is a constitutional body consisting of one democrat, one republican, and one independent, appointed by the Governor and confirmed by the Senate. The chief objects accomplished by the Commission in Lunacy are summarized as follows: (1) The reorganization of the Pathological Institute. (2) Provision for the addition of 5,147 beds to the capacity of the present hospitals. (3) The segregation of tuberculous insane, at first in solariums and tents at the various hospitals, and later by the construction of three tuberculosis hospitals, accommodating 100 each. (4) The securing of an appropriation for the construction of ten isolation pavilions for infectious diseases. (5) The passage of a law providing for emergency commitment of serious cases of insanity. (6) Large additions to the means of treatment in asylums, in the way of surgical operating-rooms, hydrotherapeutic apparatus, and numerous electrical, medical, and surgical appliances. (7) The introduction of a system of careful registration of each patient restrained or isolated, which has resulted in a large diminution in restraint of patients by mechanical means, etc., and in the reduction of the number kept in solitary seclusion. (8) Throwing open the fourteen State Hospitals to 30 clinical assistants, who have the same opportunities for study as the medical internes in our general hospitals. (9) A marked increase in the number of alien insane deported, and improving the facilities for discovering and deporting them. (10) The adoption of a more satisfactory dietary and larger ration than that allowed under the Atwater system. (11) The appointment of a medical inspector for the more continuous supervision of the 33 private asylums of the State in which about 1,000 patients are cared for. (12) Numerous systematic improvements demanded in such private retreats as did not approach the standard of care set by a general letter sent out by the Commission to the private asylums in January, 1902. (13) The development of a definite policy in the matter of provision of care of the insane by the State, which should be applicable not only now but for future years. (14) The appointment of boards of consulting specialists at a number of State Hospitals, located sufficiently near to cities, resulting in great benefits to the institutions concerned. (15) The establishment of a summer colony at the lake shore for convalescent and curable patients in connection with the Rochester State Hospital. (16) The establishment of a colony for the insane in the Champlain regions on the same principle as the Craig Colony for Epileptics, and of a Psychopathic Hospital in the City of New York.

Objection to Sanatorium for Tuberculosis.—The residents of Mt. Airy, a suburban section of Philadelphia, have been greatly agitated in consequence of the establishment there of a sanatorium for patients suffering from tuberculosis, and a number of persons have joined in a protest to the Board of Health against its continuance. It is contended that the place is not properly drained, and complaint is made of offensive odors and unpleasant sights. Twelve tents have been erected and there are about 30 patients.

The Absurdity of Phthisiophobia was strikingly shown recently in San Francisco, where, because Justice Amadée Herville, of the Tahiti Islands, is suffering from tuberculosis, the immigration authorities decided that under the law he could not be permitted to land and cross the continent to New York on his way to France. Tuberculosis was held to be a contagious disease, within the meaning of the immigration law, and Justice Herville will, therefore, be compelled to return to Tahiti or continue his journey to Europe by way of some Mexican port.

Vital Statistics of Philadelphia.—For the week ended October 22 there were reported to the Philadelphia Bureau of Health 380 deaths, as compared with 414 for the preceding week, and 390 for the corresponding week of the previous year. The largest number of deaths due to a single cause—39—were caused by nephritis; the next largest number—37—by pulmonary tuberculosis. There were reported, further, 96 cases of diphtheria, 75 cases of scarlet fever, and 62 cases of typhoid fever.

St. Luke's Hospital Income Insufficient.—At their annual meeting, on October 18, the managers of St. Luke's Hospital reported that the hospital is overtaxed, and they have insufficient facilities to handle the patients. Four wards are vacant on account of an insufficient income.

Illegal Practitioners Fined.—Four persons were convicted last week of practising as physicians without proper registration, and were fined sums ranging from $35 to $150, with the alternative of ten to sixty days in jail. Three of the number were women.

Egyptian Medical Students.—Two Egyptians, Ermia Dos and Ayad A. Ghazouli, have arrived in Cincinnati and will take up their course of study in the Medical College of Ohio. They both speak English, and have been educated by American missionaries in the American College at Assrat, and later in the Syrian Protestant College at Beirut, Syria. Their object is to return as physicians to their own country.

Cincinnati Academy of Medicine.—At the regular meeting, held October 17, a paper was read by Dr. Ferd. C. Valentine, of New York, on "The Examination of the Male Urethra."

American Nurses in Japan.—Dr. Anita McGee and her party of American trained nurses, who were a few days ago decorated by the Mikado for their services in the hospitals in Japan, left Hiroshima for Nagasaki on October 18.

First Aid on Railway Trains.—The Pennsylvania Railroad has just adopted a plan for providing first aid to the injured. It consists in equipping all baggage, mail, express, construction, and wrecking cars, terminals, yard offices, shops, and important stations with stretchers; and locomotives, terminals, yard offices, shops, and important stations with "first aid boxes." Each of these is a sealed tin box, containing six sterilized packets, consisting of one large triangular bandage, one ordinary bandage, two compresses, and two safety pins. All passenger and freight trainmen and the employees at terminals, yards, shops, and so on, where accidents are likely to occur, are to be instructed by the surgeons of the road in the primary treatment of wounds, fractures, burns, shock, etc., and the handling of the injured on stretchers. The employees will also be taught

how to treat emergency cases of unconsciousness, convulsions, and persons overcome by heat. Plans are now being prepared for the construction of a hospital car, to be used for transporting invalids.

Obituary Notes.—Dr. Samuel W. Abbott, secretary of the Massachusetts State Board of Health since 1886, and one of the best known physicians in the State, was found dead at his home, at Newton Centre, on October 22. Heart disease was the cause. Dr. Abbott was born in Woburn sixty-seven years ago, and was a graduate of Harvard Medical School in the class of 1862. He was assistant surgeon in the navy during the civil war. A widow and three daughters survive him.

Dr. William C. Flowers of Cambridge, Mass., died October 20, at the age of seventy-nine years. He was a native of Halifax, N. S., and was graduated from the Harvard Medical School in the class of 1861.

Dr. William White of Abingdon, Va., died last week in Baltimore. He was a graduate of the Medical College of Virginia in 1894.

Dr. George Purviance of the U. S. Public Health and Marine Hospital Service died in Philadelphia on October 20. He was a graduate of the Jefferson Medical College in the class of 1867, and had been stationed in Washington for a number of years.

Dr. Montefiore Levi Maduro of this city died in St. Luke's Hospital on October 22, as a result of injuries received in a bicycle accident several years ago. He was a graduate of the College of Physicians and Surgeons in the class of 1895.

Dr. Auguste Frederick Müller died at Philadelphia on October 20 as a result of malignant disease of the stomach, at the age of sixty-four years. He was born in Alsace-Lorraine, and came to the United States with his parents at the age of twelve years. He enlisted in the Federal Army at the outbreak of the Civil War, and he fought in many battles, being severely wounded in the battle of Germantown. He was graduated from the Medical Department of the University of Pennsylvania in 1866. He was long connected with the medical staff of the Germantown Hospital, and he was Vice-President of the Germantown Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

NOTES OF OPENING ADDRESSES—THE HUXLEY MEMORIAL LECTURE—BRIGHTON MEDICAL CHARITIES—SIR I. OWEN—LEEDS UNIVERSITY—PARKES' PRIZE—ITEMS.

London, October 7, 1904.

The medical schools are settling down to steady work after the more or less exciting scenes of the "opening day." It was pretty certain that the position of the University of London would be prominently mentioned by some of the lecturers, after the freedom with which all the schools had advertised their relations to it. So at University College Dr. Gregory Foster, having welcomed the students, new and old, passed on to tell them it would not be long before their school would be permanently affiliated with the University. So many schemes had been floating about for years that it was somewhat difficult to be sure what was surviving. But there was no doubt whatever that the incorporation of that college in the University would be carried out. Thanks to Sir Donald Currie's gift, that scheme had become possible and the institution would become an integral portion of the University. The preliminary and intermediate stages of medical instruction would be carried on in University College itself, the advanced stages in the hospital across the road. In the medical department Professor Norman Collie, F.R.S., gave an address on the Relation of Chemistry to Medicine.

Dr. Wethered referred to the University in his lecture at the Middlesex hospital. He commented on the fact that the largest city in the world had not yet possessed a real teaching university—an apt illustration of the difference between theory and practice. A great effort is now being made to give practical effect to the recommendation of the Royal Commission. Steps are being taken to establish an Institute of Medical Sciences near the University. Advanced studies could then be carried on at the several hospitals which would become veritable clinical schools. It was to be hoped they might see chairs of medicine and surgery endowed at the University, so that the professors might devote all their energies to teaching.

Dr. Wethered further offered excellent advice to the students, recommending them, among other things, to keep up their athletic exercises and to cultivate habits of temperance and self-control. So let them learn to live that in their future lives they might be able to draw from experience when advising their patients how to keep well.

At King's College also the lecturer (Dr. Buzzard) took up his parable about the University and strongly put forth the advantages of its degrees. He admitted that a London degree was little, if any, easier to attain than before the reorganization, and that it necessitated hard work to succeed. As to that he quoted President Roosevelt as saying, "Your work is hard. Do you suppose I mention that because I pity you? No, not a bit. I don't pity any man who does hard work worth doing." Further, he said he was inclined to allow examinations in some subjects separately, and a student who failed in one subject to come up again for it singly. The necessity of passing in several subjects at the same time tended to cramming. It is amusing to see a juggler keep half a dozen balls in the air at the same time, but there is no particular use in the achievement. Dr. Buzzard is on the Senate, so perhaps he will assist in removing from the University the reproach of promoting cramming. The rest of the lecture was devoted to the future relation of King's College to the University.

St. George's hospital kept the traditional October 1, although it fell on Saturday and the other schools deferred their opening until Monday. On the first then Professor Macalister lectured on "Some Landmarks in the History of Medical Education." He warned students that a more arduous training is required for the medical than for other professions, and that this is only to be secured by wasting no time throughout the allotted five years of the curriculum. The sciences concerned with medicine are continually growing. An element of danger in this rapid development was pointed out, viz., that as each of the fundamental sciences grows so large, it becomes necessary to appoint expert teachers and examiners. A risk, therefore, arises of the great end of training skilful and well-equipped practitioners being lost sight of. He urged, therefore, teachers to remember that each science taught is for medical students not an end in itself, but merely a means to an end. He added that the authorities should use every means to safeguard the interests of a well-balanced, efficient, professional training.

At St. Bartholomew's hospital, the address was deferred until last night, when Mr. J. Langton discoursed on "Modern Aids to Diagnosis." He feared some of the younger men might be too apt to rely on haphazard information gathered from haphazard questions rather than on the trained use of their senses. Incorrect diagnosis was often the result of carelessness. He especially dwelt on the importance of sound and light in diagnosis, and urged the students to educate their ears and eyes to the highest degree.

At St. Mary's hospital, Prof. Wright began by remarking that the twentieth century offers the spectacle of a civilization which has attained a practically complete control over the forces of nature, but utterly incomplete over the processes of disease. He passed on to point out the necessity of endowing research. He doubted if more than 100 scientific workers are actively engaged on the problems of disease out of the 40 or more millions of British people. This he considered was because such workers were face to face with the problem of primitive savages—how to find subsistence, clothes, and shelter. The solution, he said, was to be found in the provision of salaries on the scale of those obtained in civil and government services. The death duties of a single millionaire would suffice for a beginning. The comparatively simple problem of limiting the spread of infectious disease had not attracted research, though of such great financial importance, especially to schools.

At the Women's School Miss Murdoch, having commented on the great inheritance of the students undreamed of by women 40 years ago, gave some practical hints on personal hygiene. In clothes she would follow the fashion, as it would be unpleasant to be attended by a peculiarly dressed woman; but she denounced tight-lacing as well as germ-trapping jewelry. Then she pleaded for the abolition of the hat, for by exposing head and hair to sunshine and wind both would benefit. She assured the pupils that those who had never cycled without a hat had lost a great

delight. Long hatless days on the moors were worth living for and dreaming of afterwards. Nothing had done so much for women as out-of-door sports, and the bicycle had simply revolutionized and emancipated their whole lives.

Sir Wm. Macewen delivered on Monday the Huxley Memorial lecture at the Charing Cross School—the school at which Thos. Henry Huxley entered in 1842 when he was 17 years old. At the beginning of his discourse he referred to the influences under which Huxley's mind was formed, chief of which he considered were the teaching of Wharton Jones and Thomas Carlyle. To "Sartor Resartus" he referred as inculcating the love of truth which characterized Huxley. On that I pause to remark that the period of life when Sartor Resartus could be enjoyed seems rather late for inculcating the love of truth. The lecturer then expressed disagreement with the extraordinary notions promulgated by some medical men respecting the uselessness of certain organs, such as the appendix, as to which some had said that its extirpation would lessen the liability to disease.

But, asked Sir William, is this human body of ours so badly constructed that it contains many useless parts and requires so much tinkering? He might be out of fashion, but he found no such imperfections in the normal body. On the contrary, the more one looks into it and sees its work, the better one understands it, and the more is one struck with the wondrous utility, beauty, and harmony of its parts. It must be a fallacious conclusion that every organ whose use is not clear to us is a remnant of the past and useless. We have removed the spleen, one of the kidneys, parts of the brain and lungs, the patients recovering and doing their ordinary work without detriment apparent to the ordinary observer; but it would be ridiculous to conclude that these parts of the body should be removed or that man would be as well without them. One would prefer normal man as he comes into the world to the pared and mutilated animal produced by the attempts at betterment which some folks propose. From this point Sir William Macewen entered at length on his chosen subject—the Function of the Cæcum and Appendix.

Brighton has set an example of hospital management. The hospital for women there wanted to raise £20,000 to build a new hospital. The mayor (Alderman Marx) called a meeting for Monday to consider the question of amalgamation, as he thought it would be a public calamity for that amount to be spent on building when the other charities needed so much. It was agreed to amalgamate the several medical charities of the town, and in order to carry still further the work of coordination the mayor moved that a central board (to be called the Brighton, Hove and Sussex Hospitals Board) be appointed (1) to obviate overlapping of local medical charities; (2) to promote economy of administration, particularly in regard to capital outlay on buildings, and (3) to prevent the abuse of medical charities by persons not proper objects for charitable assistance. This resolution was seconded by the mayor of Hove and carried. Influential gentlemen connected with the charities were nominated to form the Board.

Sir Isambard Owen, of St. George's hospital, has been appointed principal of the Durham College of Science, in succession to the late Dr. Gurney, who lost his life in an Alpine accident. Sir Isambard is connected with the Universities of Wales and London.

The inaugural ceremony of the new University of Leeds took place yesterday afternoon, a congregation of the university being convened for conferring honorary degrees on a number of distinguished men more or less associated with Yorkshire or its college, which has now become the university. A remarkable and exceptional share in the government of this new university has been assigned by its constitution to representatives of Yorkshire local authorities—a departure from custom which the Duke of Devonshire in a speech congratulating the graduates on the event of the day pronounced to be a wise course.

The Parkes Memorial Prize Essay, awarded to Mayor Robert Caldwell, R.A.M.C., has been published by Messrs. Baillière, Tindall & Co., under the title, "The Prevention of Disease in Armies in the Field."

"Municipal Shortcomings" is the title of a volume of reprints from the Liverpool *Journal of Commerce*, dealing with the unsatisfactory state of the public health in that city.

Mr. Balfour's presidential address, at the British Association, has been published as a shilling pamphlet.

A verdict of death from misadventure was returned by the jury at the inquest on Dr. Roberts, whose decease I mentioned last week. The evidence showed that he was a victim to the habit of inhaling chloroform, and when found he had a handkerchief in his hand and a supply of chloroform in his pocket.

Brigade Surg. E. Wilson, R.A.M.C., who died suddenly last week, at the age of 76, took his M.R.C.S. in 1851, joined the army service in 1855, and retired in 1884. He served through the Indian Mutiny and took part in the affairs of the central force under Sir Hugh Rose. He had charge of the flying column in pursuit of Burgore Sing, for which he held the medal with clasp.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

HYPERGLOBULIA—INVOLVEMENT OF CONUS TERMINALIS AND CAUDA EQUINA—EFFECT OF RED LIGHT ON VACCINATION—TRACHOMA TREATED BY ROENTGEN RAYS—DIAGNOSIS FROM CEREBROSPINAL FLUID—NEW HOSPITAL FOR LUPUS.

Vienna, September 20, 1904.

Professors Goldzieher and Hochalt demonstrated a case of hyperglobulia in the Society of Hospital Physicians in Budapest. In a feeble nine-year-old girl, the left eye showed cyanosis of the retina; the right, cyanosis of the conjunctiva, ciliary injection, punctate hemorrhages of the iris, infiltration of the vitreous, and, later, profuse hemorrhage into the interior of the eye perforating the sclera. Examination of the heart was negative. The blood was highly concentrated, showing 8,000,000 red blood cells, a normal number of leucocytes, and 115 per cent. hæmoglobin. An enlargement of the spleen was evident. The picture corresponded to the obscure one described by Rendu and Widal as polycythæmia, cyanosis, and splenomegaly. Yet the Roentgen ray examination showed in the upper left part of the heart shadow a rhythmical forcible contraction, with its maximum point in the region of the left ventricle. This fact, taken together with typical club-shaped fingers, and beginning lung infiltration, and in spite of the negative physical heart examination, made it necessary to consider this a case of congenital cardiac defect.

Balint and Benedict presented three cases of involvement of the conus terminalis and cauda equina. The first case resulted from trauma; the second, from rachitis and neuritis of the roots, and the third, from aneurysm of the hypogastric artery and erosion of the sacrum. Most noteworthy was the restoration of the automatic control of the functions of the bladder and rectum, in spite of great disturbance of the sacral cord, and especially of the sacral roots. As a characteristic defect remained only a loss of function of the striated muscle of the external sphincter. On the other hand, the bladder and rectal reflexes, depending on smooth musculature, remained intact. Power of erection was not lost, though it was weaker than normal on peripheral irritation, but the ejaculation through the urethra was deficient, being under control of striped muscle. It is most interesting that in one case labor occurred, and was without pain. This can be brought forward as proof that the sensory nerves from the uterus enter through the sacral roots.

Professor Goldzieher presented four cases of trachoma treated by Roentgen rays as follows: a case of cicatrized trachoma with pannus, 2 sittings; 2 cases of trachoma complicated by pannus, blepharospasm, and photobia, respectively 15 and 12 sittings, the total duration of treatment being respectively 71 and 60 minutes; and one case of simple follicular trachoma. In each case one eye only was treated. In the first case, the treatment had to be stopped because of the extreme irritation produced; in the other cases the result was astonishingly good. The conjunctiva showed, after five or six sittings of 70 minutes' duration, an appearance such as can be achieved by applications only after years. The pannus also improved, and the subjective symptoms lessened. The other eye, for the sake of control, was treated by Knapp's method of expression. The result in the complicated trachoma was better than that with Roentgen rays. Indeed, a *restitutio ad integrum* was to be hoped for, which appeared impossible in an eye treated by Roentgen rays, because of the cicatricial changes in the trachoma infiltration. Knapp's expression is, then, superior to the Roentgen ray treatment, as that is superior to medicated applications.

Dr. Goldmann has recently recommended vaccination under the influence of red light. He called attention to its favorable influence on the vaccination process, as noted in experiments on forty children. A number of these were vaccinated on both arms, in a photographer's dark room, under red light, the dressing being thick red bandages. With the remainder, the vaccination was carried on differently, part by daylight, part by red light, and different on each arm. The result was as follows: Those vaccinations done under red light, and kept under its influence, showed no sharp reaction. The pustules were round, and sharply raised like small warts from the surrounding normal unreddened skin, while the pustules on the control arm of the same individual were broadly diffused, with much pus, and surrounded by a red inflamed area often 8 cm. in diameter. Moreover, there were swelling of the axillary glands and tenderness, conditions entirely lacking in the arm treated with red light. If the arm vaccinated by red light

was left bandaged in red for two or three days, and then exposed to daylight, it promptly showed inflammation and pustulation; and, in like manner, a milder course ensued if the arm vaccinated by daylight was dressed after two or three days with red bandages. By these experiments, then, it was learned that red light, or the absence of light of other colors, modifies the vaccination process, with its well-known formation of pustules, surrounded by an inflamed area, and also that the constitutional changes are less. That red light exerts an influence on the vaccine virus or the vaccination process seems to be established as a matter of fact, by these experiments, so an influence of red light on the course of smallpox is to be assumed. It was natural, therefore, for many voices to be raised condemning this method, and declaring that vaccination by red light would have little or no value; that the round pustules, raised on a normal skin as little warts, are such as the vaccinating physicians look upon as useless results. The flat, scarcely perceptible scar, which is even less plain after six weeks, gives the impression that here was a vaccination, the value of which against exposure to smallpox will extend at best over only a short time. Upon the duration of the immunity depends the value of vaccination, and the ten years' immunity which is now expected from a successful vaccination, is conditional upon the full development of the characteristic pustule, with its umbilication, surrounding inflammatory area, and a constitutional reaction of short duration. The characteristics of a scar from a successful vaccination are that it is not flat, involving only the epidermis, but deep, branched, and uneven, and remaining clearly visible. The discussion of this subject is not yet ended, but the majority of physicians abide by the old method.

In the Society of German Physicians in Prague, Dr. Oscar Fischer delivered an address on the "Contents of the Cerebrospinal Fluid in Progressive Paralysis." Fischer has performed numerous lumbar punctures in the psychiatric clinic of Professor A. Pick, and he demonstrated the microscopical preparations from two cases of paralysis. One of these, duration eight years, showed but little evidence of inflammation in the meninges, great increase in connective tissue proliferation, and the cerebrospinal fluid was normal in content, showing about three lymphocytes in a field 400 times enlarged. The other case ran a rapid course, lasting hardly a year. In this the meninges showed an abundant small-celled infiltration, and, to correspond, the cell elements in the cerebrospinal fluid were much increased, 30 or 40 appearing in a field. The author found explanation for these apparently contradictory results in the theory that the number of lymphocytes in the cerebrospinal fluid appears to be dependent on the infiltration of the meninges, and this again goes parallel with the acute or chronic course of the disease. The diagnostic value of the Quinke lumbar puncture for chronic diseases of the central nervous system is beyond doubt, to the extent that all diseases accompanied by organic tissue changes, as progressive paralysis, tabes, luetic affections, arteriosclerosis of the meninges and brain, multiple sclerosis, etc., at least at the time of active advance, give positive cellular results, namely, increase in the number of lymphocytes in the cerebrospinal fluid. On the other hand, functional diseases of the mind, which show no microscopical changes in brain or cord, as melancholia, paranoia, alcoholic neuroses, hysteria, and neurasthenia, show a normal number of cells in the cerebrospinal fluid. Centrifugalization is a long process because of the slight difference between the specific gravity of the cells and of the liquor cerebri. In order to shorten this process, and to obtain all the cells possible, Fischer adds a few drops of formalin solution, which forms a fine, snare-like mass of albumin, and this falls with the cells during the centrifugalization.

In the immediate future an institution, interesting from many points of view, will be opened in Vienna, namely, a hospital for the treatment of lupus. The incentive for this was in the fact that the representatives of the medical world at the International Medical Congress at Paris, realized that cases of lupus were being healed by the dozen (Lang, Finsen). They were convinced that radical methods of treatment of lupus may be successful, and that, therefore, there is a possibility of freeing from their terrible malady those heretofore completely shut out of society by their repelling appearance. This possibility awakened in Professor Lang the noble wish to call into being in Vienna an institution which would offer every method of healing for lupus, and so to create a center for scientifically established methods of procedure which ensure lasting results. Many ambulant cases will find in the new institution long-desired treatment according to new and approved methods of lupus therapy. There is ample provision also, for bed cases, especially for such as are suitable for plastic operation. In this hospital all the necessary equipment will be provided. There will be a number of Finsen lamps, Roentgen-ray and radium outfits, and an operating room. No means will be lacking that could prove of advantage to the many patients who will come from far and near. At the same time the fact is never to be lost sight of that the institution is cast in no firm mould, to the end that each new discovery for the healing of lupus can be tried without difficulty. It is intended from the very beginning to have this hospital of such a standard that it will serve as a model for similar institutions elsewhere.

OUR PARIS LETTER.

(From Our Special Correspondent.)

CONGRESS OF OTOLOGY—TREATMENT OF FURUNCLES, ABSCESSES, AND CARBUNCLES BY SUBCUTANEOUS INJECTIONS OF OXYGEN—DEATH OF WALDECK ROUSSEAU.

PARIS, September 25, 1904.

THE International Congress of Otology was held in Bordeaux in August. The first question considered was the choice of a simple and practical acoumetric formula. The only reports were by Politzer, Gradenigo, and Desaix. The second question, according to the order of the day, was the diagnosis and treatment of labyrinthine suppuration, on which Brieger of Breslau was the speaker. After having insisted on the necessity of radical trephining and opening the labyrinth, he described the technique of the operation. The other speakers on this subject were von Stein of Moscow and Dundas Grant of London. The last question was the technique of opening a cerebral abscess originating in the ear, and its after-treatment. Hermann Knapp of New York and Ricardo Botey of Barcelona were the speakers. Among other questions considered in this congress, we would mention a paper on the surgical treatment of acute meningitis of aural origin, by Lermoyez and Bellin of Paris. Also, Boulay spoke on the interesting problem of the psychological element in deafness. The congress voted that a collective investigation be organized to study adenoid vegetations and other causes of deafness.

At the Royal Academy of Brussels, Professor Thiriar recently presented a method of treating local infections by pure oxygen gas, which has the valuable property of causing the attenuation, to a great degree, of bacteria, and of destroying their toxins by oxidation. The oxygen is kept under a pressure of 120 atmospheres in a metallic case. One end of the case is fitted with an adjustment closed by an easily opened valve. To this is attached a rubber tube, terminating in a fixture to which can be fastened a simple Pravaz needle, or a small glass or rubber cannula. In treating a furuncle, one first regulates the flow of oxygen by plunging the Pravaz needle in aseptic water. The bubbling of gas in the water enables one easily to estimate the rapidity and quantity of the flow. After having previously rendered the region aseptic, injections are made in the furuncle, the needle being plunged successively into the summit and base of the tumor. At first, when the oxygen penetrates the indurated tissues, it produces a sharp pain due to distention. Almost immediately, however, the painful symptoms lessen, and soon entirely disappear; at the same time the swelling diminishes and disappears. In three or four days the furuncle no longer exists, and the rapidity of the cure is no greater than its permanence. Carbuncular infections are circumscribed or diffuse. When they are circumscribed, the Pravaz needle is used, introduced at different points in the swollen area. The current is allowed to run for about half a minute in each place, or until light digital pressure gives the sensation of crepitation, indicating that the carbuncle is, as it were, isolated in an atmosphere of oxygen. When suppuration is clearly established, and when sloughing tissue and pus are eliminated by different openings, the glass cannula is used, which passes to the center and into the ramifications of the tumor, and a comparatively strong current is allowed to run for about a quarter of an hour. The treatment is given every day for a week, and by this time the constitutional symptoms have abated, and the pus has disappeared. When the carbuncle is diffuse, it is necessary to begin by removing and carefully dissecting out the necrotic tissue, and then to direct a strong current into the center of the tumor for about ten minutes. After this a weaker current is continued for 24 hours. Five or six days are necessary to ensure complete cure. Finally, abscesses of the breast are cured by this method with incredible rapidity. The technique is simple. After disinfection, an incision is made to evacuate the pus. After irrigation by peroxide of hydrogen, a current of gas is passed for about half an hour. If the abscess is large, a permanent current is passed for 24 hours. After this time, suppuration is retarded, and in two or three days the cure is complete.

Waldeck Rousseau, the great French statesman, former President of the Council of the Ministry, died the latter part of August. He suffered from an obstruction of the bile-ducts which necessitated surgical interference, as we have previously mentioned in these letters. Professors

Terrier and Poirier performed a laparotomy several months ago, in the course of which, having found it impossible to achieve a radical cure, they had confined their attention to performing a cholecystenterostomy, in order to secure a flow of bile. The patient recovered well and easily from this first operation, but when, after several months, cachectic and feeble, he asked for a second, the French surgeons refused. It was then that the German surgeon, Kehr, in spite of the extremely debilitated condition of the patient, performed a second operation. But the illustrious patient was too feeble to stand the shock, and died a few hours after the completion of the operation.

AN INTERESTING DAY'S WORK.

To the Editor of the Medical Record.

Sir: As an illustration of the old adage that "it never rains but it pours," I have the following report to make of one day's obstetrical work. On October 5 I attended Mrs. E. M., who was delivered of twins, two girls, at 12:30 P. M. At 6 P. M., I attended Mrs. T. B., who was delivered of twins, two boys; and at 3:30 of the following morning, I attended Mrs. A. S., who gave birth to twins, two boys, making three cases of twin pregnancies attended in less than twenty-four hours.

William F. Barry, M. D.

Woonsocket, R. I.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 20, 1904.

Heart Complications in Diphtheria.—Franklin W. White from his work on a series of 946 cases of diphtheria emphasizes the following points: There is a great frequency of heart murmurs and irregularity of pulse. The prognosis does not depend upon the mere presence of these signs, but upon the severity of the infection, the length of time without treatment, the rate and degree of irregularity of the pulse and the presence of the graver signs of cardiac disturbance. Moderate disturbance of the heart is very common; severe complications are infrequent. Frequent examinations of the heart are necessary to really determine its condition, because of the marked changes in rhythm from one hour to the next. Gallop rhythm, late vomiting, and epigastric pain and tenderness are important as danger signals of severe heart complications. The association of late vomiting with gallop rhythm renders the outlook almost hopeless. Antitoxin does not affect the heart unfavorably, but, on the contrary, its early use prevents the appearance of grave heart complications. Frequent examination of the heart and pulse in the second and third week of the illness are necessary, that being the time when severe heart complications most frequently occur. Bronchopneumonia is a more frequent fatal complication of diphtheria than heart disease; sudden death from heart disease is very rare when patients are kept in bed for a proper period. Prolonged rest in bed is necessary in all severe cases; it is not necessary to keep all patients in bed who have cardiac murmurs and a pulse which is somewhat irregular and increased in rate. One should be governed by the stage of the illness and the patient's general condition. If no serious heart trouble has developed within four weeks the patients are usually safe from this complication. Heart murmurs and irregularity are of long duration in many cases, and make it necessary to watch the condition of the heart long after convalescence in all severe cases.

The Assouan Cure.—F. Gordon Morrill declares that the quality of the air of the Nubian desert differs essentially from that of any other which can be found in conjunction with the comforts of civilized life. Dryness is its main characteristic. There is also a comfortable degree of warmth. By the "invalid season" is meant the fourteen or fifteen weeks beginning about December 10. Assouan is exempt from rain and malaria. The disagreeable features consist of two or three full blown khamsins, during which one must remain indoors for an average of thirty-six hours, and a peculiar condition of the atmosphere which occurs with about equal frequency and lasts equally long—an apparent mist hangs over the Nile valley, closely resembling a fog, but due to the presence of fine sand in the atmosphere. It is safer to remain in this climate until about May 1. The diseases which derive the greatest benefit from this climate are nervous prostration, and delayed convalescence from prolonged illness; chronic bronchitis with emphysema and cardiac dilatation, with perhaps a tendency to asthma; but when the larynx or naso-pharynx are alone affected, the climate is unsuitable. Other diseases well treated here are rheumatic affections and neuralgias. This is an excellent place for the establishment of a "sand cure." Cases of prolonged albuminuria in which renal conditions render prognosis doubtful sometimes clear up completely. The writer has also observed two or three cases of incipient tuberculosis which have done remarkably well. The writer, although he does not condemn the climate of Lower Egypt, declares that it is not to be compared with that of Assouan for health seekers.

New York Medical Journal, October 22, 1904.

Quintuplets.—A case is reported by A. Bernheim. The patient was thirty-nine years of age and this was her eighth pregnancy. Five male children were born at from ten to twelve minute intervals and varied in weight from four to five pounds. All were apparently healthy and well developed. All died, however, in from four to fourteen days. The afterbirth consisted of five placentæ grown together, but each with a separate cord.

Syphilis Continuously Treated by Intramuscular Injections of Mercury Salicylate.—This plan of treatment is recommended by D. A. Sinclair. The requisites are the following: An alcohol lamp for sterilizing the needle and heating the mercury; a sixty minim subcutaneous syringe; a needle of large calibre, which should have a high polish, a sharp point, and be about No. 19 gauge, and an inch and a half long; cotton; ether or alcohol; and collodion are necessary. The site most favorable for the injection is the gluteal region, but this may be changed to the calf of the leg or the muscles of the back and chest. The part selected for the injection is bared and cleaned with a piece of cotton, moistened with alcohol or ether. The remedy is prepared in dram vials, each containing one and three quarters grains of the salicylate suspended in thirty minims of benzoniol. Allowing for waste about one grain and a half are injected, but the author has used six grains without unpleasant effects.

A Contribution to the Surgery of Nephritis.—C. W. Wile reports a case. His patient was a boy of eighteen years with the history of subacute nephritis of at least one month's duration. Two months' medical treatment were without result. The right kidney was stripped and its capsule removed. Subsequent analyses of the urine showed a reduction of over fifty per cent. in the amount of albumen excreted. A second operation was then done (on the left kidney), and the amount of albumen was reduced to but a trace. There was a marked decrease in hyaline and granular casts. The urea output remained unchanged. At the time the patient was discharged from the hospital the urine contained scarcely any casts and but a trace of albumen.

Medical News, October 22, 1904.

The Surgical Physiology of the Lymphatic System.—C. H. Mayo emphasizes the important part played by the lymphatic system in the body. For a long time it was thought that there were but two lymph ducts of entrance into the circulation—the right lymphatic duct opening into the right subclavian vein, and the left or thoracic duct which empties into the commencement of the left innominate vein. Recently, however, Leaf has found that there may be a communication between the lymphatics and small veins in the groin, and it is possible that others exist and will sometime be located. It is now generally considered that the ductless glands are drained by the lymphatics. The condition of the lymphatic system in its relation to malignant disease is of the utmost importance. It is an accepted fact that there are definite gland-fascia areas which must be removed with or at the time of the removal of the original malignant growth. The prognosis of maligant disease is modified by the age of the patient and by the lymph circulation in the area involved. Cancer in the young is rapidly fatal and early recurrence of metastasis often follows operation, the gland distribution being early involved. Old age with its disappearing lymph system may often be a more hopeful condition for permanent recovery. Cancer statistics as to cure improve with each decade of life, other conditions being equal. The writer then considers the subject of drainage. He believes that aseptic operations in regions rich in lymphatics, where the lymph circulation is but little disturbed, will not require drainage as ligation of vessels in the neck, Alexander's operation, and hernias in the inguinal region. Aseptic operations in these regions in which the lymph system is removed require capillary drainage from four to six days. Free drainage of the stump should be employed in amputation for malignant disease where the glands are removed from axillary or inguinal regions. In regions rich in lymphatics, where operations are done for septic conditions, strong antiseptics should be used on the incised surface, followed by the use of alcohol or glycerine. In the drainage of wounds it is well to make a separate incision at the most favorable point and close the original operative wound completely.

The Climate and Waters of Hot Springs, Virginia.—Guy Hinsdale says that the popularity of the Virginia Hot Springs is due to a combination of climate, a variety of mineral springs for external and internal use, a complete bathing equipment, and good accommodations for visitors. The climate is distinctly stimulant which is natural as the altitude is nearly 2,400 feet. Compared with New York,

Boston, Philadelphia, or Chicago, the air is rarer, dryer, purer, and more invigorating. The cold in winter is not so penetrating, and the summer heat is never so intense. There is, however, a wide diurnal variation in temperature. The formations of shale afford a pure and palatable drinking water. The scenery is beautiful. A striking feature is the proximity of warm springs and cold springs. The mineral springs owe their efficiency mainly to the methods used in their application. It is not claimed that the good results from bathing in these hot springs are due to absorption by the skin of the mineral constituents of the water, but rather to a temperature effect. The heat or cold stimulates the peripheral nerves of the skin, and these, in turn, favorably affect the central nervous system. Many visit the Hot Springs to restore a proper function of the stomach, the kidneys, or the liver. The use of hot baths and diuretic waters together with the other aids which are at hand accomplishes much.

Three Cases of Probable Psittacosis.—Herman F. Vickery refers to several house epidemics probably due to contagion from parrots. The symptoms of the disease are those of a grave typhoidal condition with atypic pneumonia. The onset is acute, often with chilliness or a true rigor. Exceptionally the disease begins insidiously, but in that case there is apt to be a chill when the pneumonia begins. The fever is more or less continuous, with a termination by lysis. In many cases successive foci of pneumonia develop, giving the temperature curve a recurrent type. With the onset the patient is feeble and depressed; there is usually a violent headache and dizziness. There may be delirium. Obstinate constipation is the rule, but diarrhœa is sometimes present. The spleen is always enlarged. There may be a roseolar eruption. There is a cough from the beginning. Auscultation reveals subcrepitant rales throughout both lungs. After a few days pneumonia slowly develops. In some cases there may be no evidence of consolidation. Warthin states that "the bacteriology of psittacosis and the true relations of the parrot disease to the atypical pneumonia seen in man are yet to be definitely determined." The writer has observed three cases with the symptoms above described. A parrot had just been sent to the home of these patients. The bird had a bloody diarrhœa and died. It had been kept in the sitting-room of the house. Eighteen days after the parrot arrived, the domestic who had charge of the bird, was taken suddenly ill. A few days later two members of the family also fell suddenly ill. The symptoms in all of these cases corresponded fairly well with the descriptions of psittacosis, and the disease is not easily placed in any other category. The only member of the household who escaped illness had little to do with the bird. The bacteriological report made by Oscar Richardson gave disappointing negative results, but they were of considerable importance in ruling out those diseases the atypical forms of which psittacosis resembles.

American Medicine, October 22, 1904.

The Early Diagnosis of Pulmonary Tuberculosis.—William Fitch Cheney declares that in the diagnosis of early pulmonary tuberculosis the clinical history and the physical examination are the ones of greatest importance. Sputum examination does not give information early enough. Tuberculin may give reaction when no active tuberculosis is present, and may fail to give a reaction when active tuberculosis is really present. The Röntgen ray confirms what physical examination has already discovered, but does not tell anything that cannot be found out in other ways. The writer then calls attention to three sources of error in the diagnosis of early pulmonary tuberculosis. Prejudice and bias often keep the physician from seeing what would otherwise be perfectly plain. Inattention to details is an important source of error. The changes that must be dealt with in the early stages of this disease are slight, and it is by many little things that by themselves mean nothing, but that put together mean everything, that a diagnosis must be reached. Lack of persistence in examinations is often at fault for an incorrect diagnosis. The evidence must be gone over again and again. Too much cannot be said of the value of a careful and painstaking history. In the personal history the significant point is how the patient lives. The writer believes that time cannot be better spent than in the effort to make a certain diagnosis of the early stages of pulmonary tuberculosis.

"Shorten the Time from the Cow to the Baby."—Arthur R. Reynolds lays stress on the fact that 12-hour milk is worth very much more from a dietetic standpoint than 24-hour milk. Milk may be unfit food for the young many hours before it becomes sour to the taste. Milk begins to deteriorate, as to its digestibility and wholesomeness, from the moment it is exposed to the air. It is one of the best mediums for the growth and multiplication of bacteria. In 24 hours after being drawn, unless checked by cold, there will be 400,000 microorganisms in each teaspoonful of milk. Souring is due not only to the growth of bacteria which have fed and multiplied on the nutritive constituents of the milk, thereby reducing its food value, but to their production of a special souring (lactic) acid and other poisons. Old milk not only starves the young, but it poisons them. All milk intended for the use of children should be bottled in the country, immediately after having been thoroughly cooled. The bottles should be packed in broken ice and shipped to consumers within 12 hours after bottling. The writer declares that no legislation will be enacted making the delivery of 24-hour to 36-hour old milk illegal until the public is educated to a knowledge of the evils of stale milk and its murderous effects upon the young. The writer concludes his paper with the quotation from Lord Derby: "Sanitary education is more important than sanitary legislation."

Journal of the American Medical Association, Oct. 22, 1904.

A New Method of Lateral Anastomosis.—The steps of the operation are thus described by A. Werelins: (1) Fix by guy suture the opposing surfaces of stomach or bowels and sew with a running through-and-through suture; (2) Insert a silk or tissue ligature or silver wire running into the lumen of the bowel; (3) Cover the silk ligature by folding adjacent parts of intestines over it and sew with through-and-through suture, leaving the free ends of the silk ligature on the outside; (4) An assistant holds the united tissues firmly on the opposite side of the free ends of the ligature. By alternate pulling of the right and left ends of the silk ligature, the tissues are neatly cut through and an anastomatic opening is made, the thread escaping through the minute slit between the sutures. Take one more stitch where the thread slipped through and the operation is complete. The advantage of the method is that by the last-named manœuvre the bowel is cut through without exposure of the mucous surfaces while the operation is complete at once and leaves no foreign body.

Rupture of the Mesenteric Glands During Typhoid Fever.—R. G. LeConte describes a case of this nature simulating intestinal perforation. Operation was performed, and the patient recovered. Two similar operative cases with fatal results are referred to. The author's conclusions are as follows: (1) Swelling of the mesenteric glands is a constant lesion of typhoid fever. (2) Such enlargement is due principally to a proliferation of the endothelial cells lining the lymph sinuses. (3) These cells by penetrating the walls of the capillaries and smaller veins produce thrombosis, with resulting minute necroses. (4) Such necrosis ends in resolution. (5) Perforation of the capsule of the gland is dependent on some causes other than the presence of the typhoid bacillus and thrombosis of the smaller glandular vessels. (6) Perforation is probably due either to the presence of the staphylococcus or streptococcus in the gland, or to thrombosis of larger vessels of the mesentery outside of the gland.

The Lancet, October 22, 1904.

A Case of Gigantic Renal Calculus.—The case is reported by A. Marmaduke Shield, who discourses also on other cases in which renal calculi formed obvious tumors. The patient in this special instance was a man of thirty-nine years, with the usual symptoms, which had recurred at intervals during a period of fourteen years. Operation was performed, and the stone weighed fresh, with sand and detritus, and soaked in blood and fluid weighed nineteen ounces; when dried, it weighed sixteen and one-half ounces. Its longest diameter was five inches and greatest circumference about ten inches. The patient made an uneventful recovery. The author appends a list of cases in which large stones have been removed, and believes that under such conditions the preferable operation is to remove the disorganized kidney and calculi by an anterior incision.

Chlorate of Potassium in Habitual Abortion.—This remedy is recommended by G. S. S. Hirst, who records a case in which it seemed to prove successful. The patient had previously aborted eleven times, and this time carried her child to full term, and was delivered in a normal manner of a healthy girl. For nearly four months she took two and a half grains of the drug, three times daily. No apparent cause could be found for her previous abortions, and she had always taken the best possible care of herself during her pregnancies.

A Case of Blood Poisoning from Tonsillitis.—I. Owen records the case of a man aged twenty-two years with an apparently ordinary acute tonsillitis. In about eight or nine days a condition of general sepsis set in. The swab test showed neither diphtheria bacilli nor streptococci, but a later blood test showed the presence of the latter organisms. Antistreptococcic serum was given, but without avail. Roux's serum seemed at first to give some benefit, and was given intermittently, according to indications. The greatest benefit seemed to come from giving every six hours half a dram of tincture of non-perchloride, with twenty-five minims of dilute hydrochloric acid and three grains of quinine sulphate. The patient made a good recovery.

The British Medical Journal, October 15, 1904.

Lesions of the Posterior Columns in General Paralysis.—David Orr and R. G. Rows, in their study of general paralysis, have devoted special attention to the degenerations found in the posterior columns. The spinal cords studied were treated by the Marchi method, as being the most delicate method for determining the early degenerative changes in the fibers. Besides, a modification of Weigert's medullary sheath method was used to demonstrate sclerosis, if present. Degeneration in the posterior columns has been constantly found, varying in degree in the different cases. The writers have found the following features in all cases: The portion of root between cord and posterior root ganglia shows no degeneration. Degeneration of the internal division of the sensory root in its intramedullary path, commencing at the point of entrance into the cord. The external division, or Lissauer's area, remains almost intact. The collaterals and terminals passing into the gray matter share in the degenerative process. The long fibers, derived from segments situated low down in the cord, are also affected, as shown by the presence and position of the degenerated fibers in Goll's column in the upper parts of the cord. The writers believe that the sensory fibers are specially vulnerable just where they enter the cord, owing to the absence of the neurilemma. The degeneration is primary, and due to the direct action of toxins on the myelin sheath and axis-cylinder. Owing to the damage inflicted on this latter, however, there becomes added to the original primary degeneration a secondary one. The areas affected in these cases coincide anatomically with those seen to be degenerated and sclerosed in early tabes. The writers hold that tabes dorsalis starts in the same manner, and is a chronic affection of the sensory fibers, due to the primary influence of a toxin in the posterior lymph system, which attacks the nerves at the vulnerable point. The fibers affected must be assumed to be weaker than those which are not, but the lesion spreads to the latter owing to the secondary changes induced by the degenerative products. Thus degeneration slowly merges into sclerosis.

Treatment of Pruritus Ani.—Malcolm Morris limits the term pruritus ani to a condition characterized by intense itching about the lower orifice of the bowel. Pruritus is often a symptom, sometimes an essential disease. The possible etiological factors of this affection are numerous. It is often found in the gouty, and in those who suffer from disorders of the digestive and chylopoietic apparatus. Shell-fish and strawberries sometimes give rise to it; also tobacco. Piles, constipation, fissure, ulceration, foreign bodies, and irritating discharges from the bowel or neighboring parts sometimes give rise to it. Cutaneous diseases, such as eczema, may produce the symptom. It is said that the most important predisposing cause is hyperæsthesia. General diseases producing it may be idiopathic neuroses, such as hysteria or hypochondriasis, or other affections of the nervous centers. Although pruritus ani may occur at any age, there is a certain relation of particular causes to particular ages. Thus in children, the itching is likely to be due to worms. The patient generally seeks relief in violent scratching, and thus secondary lesions develop. Pruritus ani is often very refractory to treatment. The first thing to do is to seek for the cause and remove it, or neutralize its action. The treatment must be appropriate to the cause. In all cases it is well to regulate the bowels and recommend a bland, but nutritious diet. Rich foods and alcohol should be forbidden. Short courses of calomel in small doses are useful. Tonics are indicated if the patient is depressed, with a poor appetite, and failing nutrition. Thorough flushing of the system with large quantities of weak alkaline waters is often a powerful aid to local treatment. The most scrupulous cleanliness must be enjoined. The application of water as hot as can be borne is a very efficacious method. Some patients prefer very cold water. After bathing, a soothing or cooling remedy should be applied. Local remedies may be classified as anodyne, antiseptic, and caustic. Cocaine may be used in the form of a suppository, but care should be taken that the patient is not allowed to use this remedy too freely. Menthol is cooling. A strong solution of bicarbonate or bisulphate of soda applied in a poultice is an excellent sedative. Carbolic acid often acts like a charm. Oil of cade is useful. The local application of calomel is highly praised. The calomel stops the itching at once, according to the advocates of this method. Nitrate of silver is sometimes used. The patient should be kept cool in bed. Hypnotic suggestion has been tried with success. Electricity is said to have given good results. It is well, after bathing the parts, to apply a powder like bismuth, oxide of zinc, and starch, or orthoform. However, each case must be studied as a distinct problem.

The Influence of Peripheral Nerve-Irritation upon Diseases of the Skin.—G. Norman Meachen says that although trophic disorders of the skin are well known, local irritation of terminal peripheral nerve filaments has not been so widely credited with any special influence upon the production of cutaneous diseases. Irritation proceeding from the cranial nerves, such as the ocular and the dental branches of the fifth, appear to possess an appreciable influence over the progress of certain forms of alopecia areata. The "dental theory" is an instance in point. Errors of refraction have been found to be associated with some kinds of alopecia. The appearance of herpetic eruptions upon areas of the skin which have been injured, or in which the nerve filaments are irritated, is frequently seen. Lichen planus is sometimes met with in the vicinity of old fractures, or in scratch marks. "Trophic influence" cannot always be brought in as an explanation. Conditions of "nervous erethism" are often responsible for cutaneous disorders.

Berliner klinische Wochenschrift, October 3, 1904.

Sclerosis and Dilatation of the Right Coronary Artery Through Digitalis.—Openchowski is of the opinion that digitalis has a strengthening effect only on the left heart and dilates the left coronary artery, whereas it contracts the corresponding artery on the right side and weakens the work of the right ventricle. The indiscriminate administration of digitalis is ill-advised and may lead to serious overtaxing of the right ventricle. In the author's case of advanced complicated valvular lesions on two occasions the use of digitalis was followed by aggravation of the symptoms of broken compensation, and he made the diagnosis of dilatation and sclerosis of the right coronary artery, which was later confirmed by autopsy.

Convergent Strabismus, Its Heredity and Treatment.—Cohn, from the histories of 2,700 private patients collected during the past forty years, comes to the conclusion that in 23 per cent. of the cases of strabismus some near relative was affected similarly. His general rules of treatment gathered from his experience of over 2,000 cases of strabismus and 700 operations are as follows. Up to the fourth year no treatment except to bandage the unaffected eye several hours daily at play. In the fifth year begin separate exercises by means of convex lenses and the stereoscope, and correct the total hyperopia. Tenotomy is not to be done before the tenth year, only in cases where the deformity is very great should the operation be performed as early as the sixth year. Promise improvement, but never a cure. In severe cases advance the externus.

Münchener medizinische Wochenschrift, October 4, 1904.

Preliminary Report on the X-Ray Treatment of Two Leukæmics.—Fried says that the results obtained by the *x*-ray treatment of leukæmia are sufficiently satisfactory to encourage further work in this direction. He reports two cases of his own, in which during about a month of treatment the size of the enlarged spleen greatly diminished, the red cells rose from 2,525,000 and 3,075,000 to 3,925,000 and 4,450,000, respectively, while the leucocytes dropped from 62,280 and 185,000 to 22,500 and 14,642, respectively. There was also a rise in the hemoglobin and a marked improvement in the patient's general condition. The author says it is still too early to say whether this improvement will be permanent or not and whether further amelioration is to be expected for a continuation of the treatment. It is possible that it is only the exacerbations of the disease that can be subdued by this means, and that its general course will remain uninfluenced, but further experimentation seems indicated.

The Mechanical Sterilization of Rubber Gloves.—Fromme and Gawrensky have made a series of bacteriological tests with a view to determining whether it was possible to render completely sterile by purely mechanical means rubber gloves that have been infected. Dettmer, Wandel and Höhne published results indicating that this could be effected by washing with soap and sterile water for two and a half minutes, but the authors found that it was impossible to ensure sterility in this way. They always observed growths in the culture medium unless the washing process was concluded with the use of an antiseptic solution (1-1,000 bichloride). They explain this discrepancy by attributing the results of former authors to the fact that they used as nutrient medium agar, which is less adapted for the growth of the germs concerned than is bouillon, which was the culture medium employed by themselves. Their conclusion is that it is safe to perform minor operations with rubber gloves that are put on in unsterile condition and then washed for four minutes with soap and water and for two minutes longer with bichloride solution. It is, of course, essential that the glove be without holes and that it fit well.

The Comparative Results Obtained by the Ferrometer and Hæmoglobinometer.—Altmann made parallel determinations on thirty patients by means of the Fleischl hæmoglobinometer and the new ferrometer of Jolles. By suitably graduating the size of the cylinder and the quantities of reagents used Jolles has adapted his apparatus to the Fleischl-Mischer hemoglobinometer so that the glass wedge

of the latter may be used as a standard of comparison. The method is therefore much simplified and according to the author may be carried out in fifteen minutes. In the author's thirty observations the two methods corresponded very closely in all but three cases. These were of anæmia, Addison's disease, and diabetes, and the author concludes that the ferrometer determinations on the one hand are valuable controls on the hæmoglobinometer figures, and on the other that where marked variations are observed these may be of clinical significance.

Deutsche medizinische Wochenschrift, October 6, 1904.

Intestinal Obstruction.—Roos reports a case of intestinal obstruction in which atropine was used with good results. The patient was a woman of fifty-one who had a ventral hernia following laparotomy. For eight days she suffered from intestinal obstruction supposed to be due to the hernia. All operative treatment was refused and the case seemed hopeless when 2 mg. of atropine were given internally. There was no effect and the next day 3 mg. of the alkaloid were injected subcutaneously. A few hours later flatus and feces were passed in abundance. The pulse rose to one hundred and forty, but no other symptoms of intoxication were produced. Four months later the same condition developed, but the atropine treatment proved ineffectual, and the patient's death was hastened by a complicating pneumonia. In another case a woman of sixty-three years, after several years of dyspepsia, had an attack of localized peritonitis in the region of the gall-bladder. Five months later after protracted colicky pain and intestinal obstruction a gallstone measuring 4.3 cm. by 2.8 cm. was passed, and the patient recovered. The author ascribes the first attack to the perforation of the gall-bladder and transit of the stone into the intestine.

Applications of Continuous Local Pressure.—Heerman describes his method of employing continuous local pressure over swellings of all sorts either by the old but little used sponge compression or by the use of suitable inflatable cushions of rubber. The essential point in applying such agents is to have the outer bandage of absolutely unyielding material. The ordinary flannel or muslin bandage will not do, and the author employs straps with buckles which are applied either singly or in combination. If a sea sponge is used it is applied to the part moist and is dampened several times throughout the course of the day. Inflatable cushions are applied flat and then blown up after the outer constricting bandage is in place. In one case of swelling of the leg following a blow the author made use of the inner tube of a pneumatic tire which was applied down one side and up the other of the leg. The scope of the method is very large, and the most varied conditions such, for example, as contractures of the fingers due to cicatrices, etc., can be relieved by its means.

The Operative Treatment of Cicatricial Contraction of the Cheek.—Manasse describes the difficulty of relieving the deformity and loss of function attending the contraction of the soft parts of the cheek sometimes following severe cases of such conditions as burning by caustics, stomatitis due to scarlatina, smallpox, measles, etc. Very few instances of permanent cure are on record, and the author reports a recent case in which he successfully treated such a condition by an extensive plastic operation. The patient had acquired his deformity in childhood following an attack of facial erysipelas, during the course of which the mouth was frequently cauterized with silver nitrate. Three previous operations were followed by recurrence. The author divided the scar tissue on either side and transplanted into the gaps pedicled flaps taken from the sides of the neck and twisted so as to cause the skin surface to face into the mouth. The skin of the cheeks was disected up and drawn over the raw gap. The functional and cosmetic results were excellent and are still unchanged fifteen months after the operation.

French and Italian Journals.

An Anti-Rheumatismal Serum.—The discovery of Menzer, a physician of Halle, of a curative serum for articular rheumatism, seems full of promise. In the two years in which Menzer has been studying this question, he has become more and more convinced that this disease is caused by a streptococcus which enters the organism through the lungs. His treatment has been equally successful in cases of acute and chronic rheumatism.—*La Revue Médicale du Canada*, September 28, 1904.

The Urinary Eliminations in the Course of Uncontrolable Vomiting of Pregnancy.—M. A. Schwab being impressed with the fact that if rational therapeutics are to be used it is necessary to understand the etiology and pathogeny of a disease, has reviewed some of the work that has been done in relation to the urinary elimination in the cases of uncontrollable vomiting, thinking in this way more light may be thrown on the obscure problems associated with this condition. It has been determined that the diminution in the quantities of urea and chlorides is more marked as denutrition is more accentuated. From observations which have been made he presents the following data. Diminution in the chlorides is constant; in five cases the weight of sodium chloride eliminated in 24 hours was less than 2 grammes. The diminution in phosphates is also constant, but within far narrower limits. The quantity of urea was normal in two cases, and clearly below normal in four other cases. The quantity of uric acid was more than normal in three cases, normal in two cases, and less than normal in one case. The relation between uric acid and urea was considerably increased in four cases, and diminished in one case. The relation between phosphoric acid and urea was normal in three cases, and increased in three others. Indican or the phenols were present in four cases. Urobilin, indican, or acetone was often noted. The writer declares that these interesting researches deserve to be continued.—*La Presse Médicale*, October 5, 1904.

Demonstration of the Specific Parasite in a Case of Rabies in Man.—Lina Luzzani records the pathological findings in a case of rabies furiosa, in a child of 10 years, bitten by a dog that escaped and of which no examination could be made. In about six weeks after the bite she developed the symptoms of rabies furiosa, and died within twenty-four hours. Careful examination was made of all parts of the nervous system with reference to the presence of the protozoa discovered by Negri. The endocellular parasites were absent in the pons, bulb, and medulla; numerous in the cornu ammonis, cerebellum, cerebral cortex, Gasserian gangion, ganglia of the vagus, and superior cervical ganglia of the sympathetic. In the salivary glands and the skin of the wound they were absent. They were typical in form, but smaller in size than those found in the dog, due, perhaps, to the shortness of the illness. This case corresponds with the reports of the disease in dogs; in the furious form the parasites are frequent in the brain and ganglia; in the paralytic form they are frequent in the spinal ganglia and medulla and infrequent in the cerebrum. —*Archivio per le Scienz Mediche*, Vol. XXVIII, No. 11.

Plaster Apparatus in the Treatment of Pott's Disease.—P. Desfosses and G. Berruyer conclude their article on this subject. As to the length of time that apparatus should be worn by patients suffering with Pott's disease, the writers declare that in childhood the parts of the body change very rapidly. A child that is well fitted with apparatus when it is first applied, may be found to be uncomfortable or even suffering with excoriations four months later. The plaster corset should be changed every two or three months. The child with Pott's disease should in the beginning be kept lying down until the phenomena of pain or of paraplegia have disappeared. At the end, perhaps of two years, if the pain has completely ceased, if the paraplegia has disappeared, and if the abscess has healed, walking may be allowed, and for this purpose the child should be provided with a Sayre corset. It must be added, however, that certain children do badly when they are kept for a long time in bed. Their nutrition suffers, and their intestinal functions are interfered with. In such cases showing an intolerance to rest, it is indispensable to have recourse in the beginning to Sayre's corset, and to permit walking. But this treatment is the last resource. Horizontal decubitus ought to be the rule in the treatment of Pott's disease.—*Le Bulletin Médical*, October 5, 1904.

Malaria and Ascarides.—H. Gros reports a very interesting case in which infection with the ascarides was present at the same time with an attack of malaria. The patient was a man of 40 years who had been troubled with "worms." When he entered the hospital he had been sick for about eight days. He complained of headache and anorexia. He had fever, and vomiting, accompanied by great nausea. There were pains in the abdomen and diarrhœa. The patient was very weak, his body was covered with a cold sweat and the abdomen was swollen and painful on pressure. The pulse was 140 a minute. Poultices were applied to the abdomen, and an opium derivative was given. On the next day the patient had a violent chill, and the temperature rose. Calomel and santonin were given. The writer refrained from giving quinine, as there was no immediate danger to be feared from the patient's condition. On the next day the vomiting occurred again, and the patient thought that he was going to die. There were 3 liquid stools in which 2 ascarides were passed. Feeling better, he returned to his home in the evening. Before he left the hospital he was given sulphate of quinine, and some of the same drug was given him with directions to take it morning and evening for 3 days and to return to the hospital within a few days. He did not return, but his brother came to the hospital with a well-defined attack of malarial fever, the malarial organisms being found in the blood. The first patient was reported to be perfectly well. The writer believes that the first patient had an attack of malaria, with the presence of ascarides in his intestine at the same time. The malarial organisms, however, were not found in his blood.—*Le Caducée*, October 1, 1904.

Book Reviews.

Clinical Vibration Charts. By M. L. H. Arnold Snow, M.D. New York: The Scientific Authors Publishing Company, 1904.

These charts are designed to aid the practitioner in the therapeutic application of vibration and of high frequency currents. Chart I. shows the relation of the sympathetic ganglia to the vertebræ, and the origin and distribution of the great plexus of the sympathetic. A cross section of a dorsal vertebra shows the relation of the sympathetic and spinal branches. A table of referred pains is appended. In Chart II. the relation of the segments of the spinal cord and their nerve roots to the vertebræ is shown. In a table of spinal stimulation are given the indications for spinal stimulation for the relief of various conditions.

Essentials of Diseases of the Eye. By A. B. Norton, M.D., Professor of Ophthalmology in the New York Homœopathic Medical College; author of "Ophthalmic Diseases and Therapeutics," etc. Philadelphia: Boericke & Tafel, 1904.

The volume is one of 349 pages, and is well printed. There are no illustrations. The object of the author is to supply a work from which all theories, technical terms and phrases are excluded, to present "the essential features of eye diseases, together with their homœopathic treatment." It is a simple, brief statement of the conditions attending the ordinary diseases of the eye and its adnexa, their cause and treatment. The text is divided into twenty-one chapters, which are arranged in logical order. The work will prove of value to students and practitioners of the homœopathic school, and to those who desire to know something of homœopathic therapeutics in eye diseases.

Clinical Lectures on Mental Diseases. By T. S. Clouston, M.D., F.R.C.P.E. Sixth Edition. Philadelphia and New York: Lea Brothers and Company, 1904.

In this series of lectures, so many cases of mental disease are given as almost to overshadow the subject matter proper, which in itself would make a volume of fair size and great interest. The histories are given in detail, and so vividly that the reader seems in reality to be present at a clinic, where he is under the instruction of one interested in pathology, in disease, but preëminently in the welfare of human beings. This style is that of a conversational lecturer, though never does it lose dignity of attitude nor of wording. Aside from the clinical pictures presented, the book's greatest value lies in the methods and results of treatment, which are given in full, whether or not the result was favorable. Though the author acknowledges the therapeutic limitations of the present, he seems to impersonate the modern spirit of devotion and optimism which will not rest till it has found a cure even for the incurable. The present edition gives the author's conclusions to date in connection with the cases which have changed or confirmed those previously expressed. Moreover, the book is largely reillustrated by new pathological plates.

While it is recognized that the "classification of the future will be on a pathological, toxæmic, and bacteriological basis," the classification used is based on symptoms, supplemented by specific forms of disease, diagnosed according to pathology.

The Practice of Obstetrics. Designed for the Use of Students and Practitioners of Medicine. By J. Clifton Edgar, Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College; Visiting Obstetrician to the Emergency Hospital of Bellevue Hospital, New York City; Consulting Obstetrician to the New York Maternity Hospital. Second Edition, Revised. With 1,264 Illustrations, including five colored Plates and 38 Figures Printed in Colors. Philadelphia: P. Blakiston's Son & Co, 1904.

Although less than a year has passed since the issue of the first edition of this work, several alterations and additions have been found necessary. The section on the toxæmia of pregnancy, embodying the results of Ewing's researches and deductions, is especially noteworthy. The author has given considerable space to this subject, inasmuch as the interest of the profession at large needs to be aroused so that the data and theories may be more complete. In this issue the author also seizes the opportunity to make his position more clear on the indications for embryotomy and cæsarean section, which he thinks has been misunderstood. The section on the fever of the puerperium has been entirely re-written and incorporates all that is new.

As a whole, the work is particularly well arranged; but from the students' standpoint the work is too large to be digested in these days when so much is to be learned. The subject matter dealing with the essentials is more apt to be grasped if presented in condensed form than when such a complete volume is used as a text-book.

A Handbook of Surgery, for Students and Practitioners. By Frederic Richardson Griffith, M.D., Surgeon, Bellevue Dispensary; Assistant Genito-Urinary Surgeon at the New York Hospital (Home of Relief); Past Acting Assistant Surgeon, Third Regiment Infantry, N.G.P.; Fellow of the New York Academy of Medicine; Associate Editor of the *Medical Critic*, etc. With 417 illustrations. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

Within the compass of 540 12mo. pages the author has endeavored to compress "a brief outline of the principles and practice of surgery," capable of serving as "a working guide for the student and general practitioner." The book includes not only general surgery, but also the specialties—eye, ear, nose, throat, gynecology, and genito-urinary diseases; hence the space left for general surgery is not very large; it is further reduced by several space-consuming illustrations and by page upon page of matter that has little or no rightful place in a hand-book of surgery. Thus, there are sections on uranalysis, histology, classification of disease, signs of death, autopsy, poison tests, life insurance examination, medical jurisprudence, infanticide, rape, etc. More space is devoted to the section on autopsy than to the whole chapter on tumors; cæsarean section is disposed of in a dozen lines, while sexual perversion consumes nearly a page. In many instances the compression has been carried to such an extent that the statements given have practically no value. The book needs revision and pruning in order to meet the wants of the student and the general practitioner.

A Manual and Atlas of Medical Ophthalmoscopy. By Sir William R. Gowers, M.D., F.R.C.P., F.R.S. Fourth Edition. Philadelphia: P. Blakiston's Son and Company, 1904.

In the present edition of this work such additions have been made "as are needful to represent accurately current knowledge." The most obvious change is the substitution of autotype plates, reduced facsimiles of sepia drawings by the author for the chromolithographic illustrations. The plates, ten in number, are accompanied by illuminating descriptions, and succinct histories. The scope of the work is but little altered. It includes an explanation of the value of the information given by ophthalmoscopy in diseases of other than ocular origin; instruction in the use of the instrument; a detailed account of changes visible in the eye; and a description of those changes found in special diseases. Those found in diseases of the nervous system are treated with greatest detail.

The writer speaks always as one having authority, and we have no wish to gainsay him, even though his most positive and wide-reaching statements are unsupported by given statistics. His vast experience and the enormous bibliography cited preclude the thought of errors from ignorance. His conclusions are evidently drawn from actual cases, though the cases referred to are treated but briefly and for exact illustration of the point in hand. The book is notably well arranged, clear in style, and is evidently written for those to whom the rudiments are an old story.

An Atlas of Human Anatomy, for Students and Physicians. By Carl Toldt, M.D., Professor of Anatomy in the University of Vienna, assisted by Professor Alois dalla Rosa, M.D. Translated from the Third German Edition and Adapted to English and American and International Terminology by M. Eden Paul, M.D., Brux., M.R.C.S., L.R.C.P. Fourth Section, *E.* Splanchnology (figures 641 to 932 and Index), and Fifth Section, *F.* Angeiology (figures 933 to 1123 and Index). New York: Rebman Company, 1904.

It is difficult to give an adequate review of these unequalled anatomical atlases in the limited space at our command. One would need a couple of pages at least to point out the excellencies of the delineations of various organs—digestive, respiratory, and genito-urinary—of the human body, to note the disagreements (for doctors do disagree even over the facts of anatomy) between the authors and other authorities in this science, and to comment upon the several pages of most valuable notes, which the translator has appended to each volume.

In Part IV, after a preliminary consideration of the structure of organs in general, the secreting and absorbing apparatus, the digestive and respiratory organs are pictured; then follows a section on the topographical anatomy of the thoracic and abdominal viscera, and this is followed by plates depicting the genito-urinary apparatus, the male and the female organs of generation.

Part V treats of the circulatory systems, blood and lymphatic; of the anatomy of the heart, vessels, and lymphatic glands, and of the distribution of the blood-vessels and lymphatics.

A sixth part, on neurology and the organs of special sense, will complete the series.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, Held in Cincinnati, Ohio, October 11, 12 and 13, 1904.

The Association convened at the Grand Hotel, under the Presidency of Dr. Hugh T. Patrick, of Chicago.

Prayer was offered by Rev. Chas. Frederick Goss, after which the Mayor of Cincinnati delivered an Address of Welcome, which was responded to by Dr. Dudley S. Reynolds, of Louisville.

The Choice and Use of Medical Literature.—This was the subject of the President's address, delivered by Dr. Hugh T. Patrick, Chicago. He said the daily walk of doctors differed greatly. We had the family factotum, the conversational doctor, the lodge doctor, the church doctor, the society doctor, and the doctor deep in politics. They were good friends and good citizens, but really fine physicians? Not one of them. And not one of them knew or cared about good medical literature. The wise, skilful physician he would like to be, read a great deal. He selected his literature well and used it wisely. The selection of books was a task as delicate, a duty as significant as was the choice of drugs. Every book was a prescription for one's mental self. Progress meant expansion. No textbook doctor was an A No. 1 man. He must have the treatise, the system, the cyclopedia, and the monograph. Of all books, the monograph was the best and the worst. It must be properly selected and read with discrimination. In medicine there was no such thing as an authority. Every paragraph was to be adjudicated. Concerning medical journals, the speaker said: "Since to advise is more human than to confess, to find fault more spontaneous than to praise, to say don't easier than to say do, I venture first to advance a few of the don'ts in my mind. Don't admit to your presence a journal that is not perfectly straight and clean. Don't indulge in yellow journals, for such there are of deeper or fainter dye. Don't take a journal which is run as an advertising medium. Don't tolerate the journal that accepts abortive papers by underdone doctors. Don't waste time on journals abounding in short cuts. Don't pay much attention to columns of formulæ, notes on treatment, therapeutic hints, brief paragraphs on recent discoveries, and items on new drugs." In conclusion, four hints were given as to the manner of reading: "(1) Systematically, to get up one subject well; to investigate it thoroughly in every way. Then take up another. (2) To read up fully on cases in hand. No case can be considered alone. It is always in relation to variant cases. (3) Reading to write, providing, of course, that the writer compels himself to produce really good material. Pursuance of these three plans produces a most desirable habit—the keeping of case records. This in turn stimulates reading, and enhances its value. Accurate comparison of experience ripens knowledge into wisdom. (4)To acquire the mental habit, or attitude, or aptitude of reading for reproduction. There is a vast difference between the acquisition of knowledge as a mere accomplishment, and as a means of accomplishment. It is well for us doctors to regard our store of knowledge not simply as an interesting museum of nature's wonders, marvelous to contemplate, but rather as an armamentarium, an orderly array of goodly weapons ready for instant use."

Surgical Tuberculosis in the Abdominal Cavity, with Especial Reference to Tuberculous Peritonitis.—This was the title of the Address on Surgery, delivered by Dr. William J. Mayo, Rochester, Minnesota. In St. Mary's Hospital during the ten years from October 1, 1894, to October 1, 1904, 6,408 abdominal operations were performed; of these, 183, or a little less than 3 per cent., were for tuberculous lesions. Localized in intestine, 21 times; in appendix, 29; in Fallopian tube, 44; and tuberculous peritonitis, 89. Of the latter, not over fifty per cent. remained well, although 96 per cent. were discharged improved or cured, giving a high percentage of relapses within two years. About four females were operated upon to one male. In seven relapsing cases in females, reinfection was found to arise from tuberculosis of mucous membrane of the tube. In all, 26 cases of tuberculous peritonitis in females were subjected to radical operation for the removal of tuberculosis of Fallopian tubes. In a few females an infecting focus was found in the appendix or cæcum. In a minority the source could not be traced. In men a considerable number arose from tuberculous lesion of the appendix or cæcum. Tuberculous peritonitis, like septic peritonitis, was due to a local focus. A considerable number of cases of tuberculous peritonitis were cured by nature. Simple laparotomy aided recovery by permitting of more thorough encapsulation of tuberculous products and by increasing the anti-tuberculous serums in the abdominal cavity. Removal of the localized focus of infection in the tube, appendix, etc., would greatly increase the percentage of cures and prevent reinfections. If the local focus could be removed and was primary, a general cure might be expected. If secondary to a primary disease in the lung or other part of the body, ultimate recovery depended on curability of the chief lesion.

A Plea for Wider Knowledge Concerning Diseases Which Affect the Joints.—This was the title of the Address in Medicine, by Dr. C. Travis Drennan, Hot Springs, Arkansas. The author urged the necessity of greater care in every instance in which a joint was involved, no matter how insignificant such condition might appear. The usual cases of acute articular rheumatism, gout and tubercular disease could easily be recognized under ordinary conditions, but not so much could be said when one came to the early manifestations of arthritis deformans, so-called subacute articular rheumatism, and certain forms of gonorrheal arthritis. Under existing knowledge it was well-nigh impossible in certain cases to differentiate these diseases during their earlier manifestation. When the etiology of gout was written, in his opinion it would be shown to manifest itself primarily somewhere along the digestive tract. If we could get perfect digestion, we were in a position to get perfect assimilation, and with perfect assimilation, most assuredly we were in direct line to get perfect elimination. That there was a nervous element supervening in arthritis deformans, was a view concerning which he had a well-grounded belief.

Hospital Construction in American Cities and Towns.—Dr. A. J. Ochsner, Chicago, in a paper with this title pointed out the fact that an enormous number of new hospitals had been established, and were still being established in every part of this country; that so far the new hospitals had almost all been built by architects who based their plans on the principles which governed hospital construction thirty years ago, at which time the theories of contagion and infection were wrong. Nothing was known about differences in purity of air at different levels. The elevator had not been perfected. It was not possible to make high buildings fireproof at a reasonable cost. These changes in our knowledge being of the greatest importance should change entirely the plans of hospital construction. The importance of proper location was discussed at length. The building should be so placed as to admit sunlight to all the rooms and wards. It should be accessible to the patients and their friends and to the medical staff. This could usually be accomplished without interfering with the other important conditions. The paper then gave a number of plans for hospitals intended for various purposes, the latter being those exhibited at the Louisiana Purchase Exposition by the author, associated with Mr. M. J. Sturn, architect. Stress was laid upon the fact that millions of dollars would be spent in the construction of hospitals in the immediate future, and that it was important that the subject be thoroughly studied in the meantime.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Bransford Lewis, St. Louis, Missouri; *First Vice-President*, Dr. Frank P. Norbury,

Jacksonville, Illinois; *Second Vice-President*, Dr. J. Henry Carstens, Detroit, Michigan; *Secretary*, Dr. Henry Enos Tuley, Louisville, Kentucky, re-elected; *Assistant Secretary*, Dr. John F. Barnhill, Indianapolis, Indiana; *Treasurer*, Dr. S. C. Stanton, Chicago, Illinois.

Indianapolis, Indiana, was selected as the place for holding the next annual meeting; the time, second Tuesday, Wednesday, and Thursday in October, 1905.

Medical Section.

What Shall be Done with the Criminal Insane?—Dr. John Punton, Kansas City, Missouri, in a paper with this title, said that the conflict of authorities in law and medicine was responsible for much miscarriage of justice. The members of the American Psychological Association and the general medical profession were appealed to for their assistance in defining the mental condition which should exonerate a criminal from punishment. The wide difference of opinions prevalent in the public and professional minds relative to what constituted criminal responsibility of the insane rendered a consensus of medical opinion a necessity. Very few of the insane were wholly irresponsible for their misdeeds, and they should, therefore, incur, with certain restrictions, some form of punishment. The declaration of the law that the insane man was wholly irresponsible was a gross confession of weakness. Some courts recognized modified responsibility and instructed the jury to commit the insane criminal, if found guilty, to the State Insane Hospital until his recovery, when he should again be set free, and this usually happened a very short time after punishment. The just or humane medical disposition of the criminally insane would seem to demand his incarceration in a special institution under medical surveillance and subject to certain restrictions suited to each case, and he should never be allowed to associate with innocent inmates of the State Insane Hospital.

Dr. A. Ravogli, Cincinnati, deprecated the tendency to generalize too much in discussing the criminal insane. He reported a case in which an epileptic committed several murders before his insanity was recognized.

Dr. Charles W. Hitchcock, Detroit, said this was a very delicate question, and a case was reported, showing that justice might miscarry.

Dr. G. Frank Lydston, Chicago, said that the entire subject of criminology should be relegated to the medical profession, so far as the physical conditions and remedies therefor were concerned. Both sane and insane criminals should be removed from our social system and isolated. The principle should be not punishment, but simply social self-defense. What should we do in regard to the propagation of the criminal insane? We had not yet come to the sterilization of these individuals, but undoubtedly would do so.

Dr. F. W. Langdon, Cincinnati, said that if the profession was given full power in this matter, it was questionable whether it would be able to draw the lines satisfactorily. The legal and medical professions had different points of view, and therefore their conclusions must vary.

Dr. B. F. Beebe, Cincinnati, stated that law had been coming to medicine on this question, because the prosecutors had been securing the assistance of medical men. Society must be protected, but the question was how and when and where to take care of the criminal insane. We must determine what constitutes responsibility or irresponsibility.

Dr. Dudley S. Reynolds, Louisville, spoke of the qualifications of the jury, requiring that they be not familiar with the facts and were not opposed to capital punishment. Such qualifications did not require that the jury be really competent to decide these cases, and medical men were called in to testify as to the responsibility or irresponsibility of the defendant. Medical testimony was based not on an examination of the individual, as a rule, but upon hypothetical questions constructed by the legal gentlemen. Any person convicted of a felony should be unsexed rather than killed. No person in his right mind would commit a felony.

Dr. Sprague referred to the fact that the use of the asylum for the criminal insane was being rapidly extended throughout the country. Often the attorneys for the prosecution and defense agreed to rest the matter of commitment or trial with the medical commission of such an institution. Such a reference would be more frequent if there were more assurance that such a medical commission was composed of really expert medical men.

Dr. Lydston, in answer to a question, stated that sterilization could be effected by obliteration of the Fallopian tubes in the female, and by obliteration of the vas deferens in the male, without any effect upon the individual, save the arrest of the function of procreation.

Dr. Punton, in closing, said it was desirable that the court should properly instruct the jury in these cases.

Loss of Consciousness and Automatism in Inebriety.—Dr. Thomas D. Crothers, Hartford, Connecticut, said that the claims of no recollection or consciousness of events by inebriates indicated a paralysis of certain brain sections during which the victim might act automatically and be without consciousness of the real condition.—Histories of prominent cases confirmed this fact. Many startling crimes were committed in this condition. This was a new phase of irresponsibility which had not been recognized by the courts, and only recently had been studied by psysicians. The defense of no recollection might be a reality in some cases, and should be recognized by physicians.

Dr. B. F. Beebe stated that the essential point was to prove the fact of the unconsciousness and the automatism. An idea could not exist if the brain cell was not in a condition to receive and retain an image. Whether unconsciousness was produced by alcohol or any other poison, the result was the same.

Dr. John Punton said that the medical profession ought to know the effects of alcohol upon the nerve cells, but when this question came up in court there were as many opinions as there were doctors.

Dr. Hugh T. Patrick said it was necessary to make a very fine distinction between alcoholic automatism and automatism in the alcoholic. In many degenerates or imperfects, there was a tendency to drink too much. The automatism and the drinking might be the result of a pre-existing condition.

Dr. Crothers, in closing, stated his belief that individuals, such as he had described, should be regarded as insane.

General Streptococcus Infection of Intestinal Origin.—Dr. G. W. McCaskey, Fort Wayne, Indiana, read a paper on this subject, in which he said that there were constantly in the respiratory, genito-urinary, and digestive tracts large numbers of pathogenic germs, which might exist in any one of three states: (1) Actively virulent; (2) innocuous, but with conservation of virulence; (3) as pure saprophytes. These pathogenic germs, which included streptococci, staphylococci, the colon bacillus, and many others might be transformed from the saprophytic to the virulent state by local or general morbid condition. In the case reported, a girl, aged 20, a severe chilling of the surface led to a general infection by the streptococcus pyogenes, which apparently had its origin from the intestinal contents which were almost a pure culture of this organism. No other possible source of infection could be determined.

Hereditary Predisposition in Tuberculosis.—Dr. Charles L. Mix, Chicago, said that hereditary predisposition was usually defined as a specific predisposition toward tuberculosis. The nature of such predisposition was purely speculative. The argument in favor of hereditary pre-

disposition was as follows: Tubercle bacilli were ubiquitous; every one was constantly breathing them in. Half of the people became tuberculous; half escaped. Half were, therefore, predisposed, and half were immunes. The major premise was false, as shown by a table illustrating the number of individuals to each consumptive. The table explained the maximum incidence of tuberculosis at the ages of from 20 to 35 years. There were many fallacies in the usual statistics tending to support the theory of hereditary predisposition. The reports of the numerous joint investigation committees proved nothing. The interpretation of the family cases of tuberculosis was often faulty; family cases showed infection just as much as hereditary predisposition. Hereditary predisposition implied hereditary immunity, but the latter apparently had no existence. The conclusion was reached that there was no such thing as specific hereditary predisposition.

Dr. G. W. McCaskey agreed with the author that there was no such thing as a specific hereditary predisposition to tuberculosis. The important thing to remember was that tuberculosis was always an infection, and that no one could ever contract the disease unless infected. There was little doubt that every one living in a civilized community inhaled tubercle bacilli at one time or another, and with more or less frequency, the inoculations proving effective or otherwise, according to the local and constitutional states of the individual.

Dr. A. P. Buchman, Fort Wayne, said that one did not invariably become tuberculous upon exposure to the tubercle bacillus; otherwise, every one would be tuberculous. Often tubercle bacilli might be found in the absence of manifest tuberculous infection.

Dr. Mix, in closing, said acquired predisposition existed, and the individual might also inherit a predisposition, not only to tuberculosis, but to any of the infections. There was no specific predisposition to tuberculosis, nor any other infection.

Treatment of Tuberculous Pleurisy.—Dr. James A. Burroughs, Asheville, N. C., referred to the use of intrapleural injections of nitrogen gas, and reported some cases in which he injected the pleural cavity with salt solution for the control of pulmonary hemorrhage in tuberculosis.

Dr. N. McKitterick, Burlington, Iowa, said that injections into the pleural cavity in the presence of diseased lungs and pleura, to compress the lung, was positively dangerous. The method did not merit much consideration in the statistics given by the essayist.

Dr. Carl von Ruck, Asheville, agreed with the previous speaker as to the dangers of pleural injection. In tuberculosis of the lungs, the cavities tended to work towards the pleural surface of the lung. To prevent rupture, nature caused a thickening of the pleural surface of the lung at that point. The injection of air or fluid into the pleural cavity to bring about the control of pulmonary hemorrhage through pressure required the breaking-up of the adhesions which nature had formed, in order to accomplish compression of the lung.

The Obstetric Significance of the Transverse Diameter of the Pelvis.—Dr. Joseph B. De Lee, Chicago, in a paper with this title enumerated the various kinds of pelves, aside from spondylolisthetic and kyphotic pelves, in which there was a diminished transverse diameter. These were especially the funnel-shaped, the assimilation, the masculine, and the infantile pelves. Various methods had been employed in making the diagnosis of lessened transverse diameter of the pelvis. The essayist presented an instrument for measuring the diameter of the pelvis. He believed the transverse diameter was not infrequently reduced. In such cases there was frequently difficulty in delivery, especially in the passage of the shoulders and the extraction of the aftercoming head. In treatment, the expectant method should not be tried too long. Frequently the forceps sufficed to effect delivery. Not infrequently symphyseotomy might be indicated. In breech cases delivery might often be facilitated by the application of forceps to the aftercoming head. Illustrative cases were reported.

Dr. Henry F. Lewis, Chicago, said the contraction of the transverse diameter of the pelvic outlet was probably more frequent than was generally supposed. In these cases one should not delay the use of the forceps, which should be applied early. In cases of infection in the male type of pelvis, when the head had well advanced, if the forceps failed, symphyseotomy was often an ideal operation.

Dr. De Lee, in closing, stated that in a breech case we were formerly instructed to put the forceps in our pocket. In such cases, we would now put the forceps on to boil. As a matter of fact, the forceps would fit the aftercoming head better than when the head presented. The exaggerated lithotomy position was sometimes of value. He reported a case in which an assistant performed tracheotomy on the child in a breech case. The child lived.

Hydrotherapy in Nervous Diseases.—Dr. Charles W. Hitchcock, Detroit, Michigan, showed that water might be made a promoter of elimination and a stimulant to all the vegetative processes. Properly applied, it was a powerful tonic. It might be an excitant, but it was also the finest sedative at our command. The author presented the practical advantages of the use of water in the treatment of neural and psychic cases.

The Treatment of the Morphine Habit.—Dr. Curran Pope, Louisville, Kentucky, in a paper with this title, pointed out the peculiar state of mind of these patients and the necessity of appreciating it. A sympathetic understanding of the needs would facilitate treatment. Too much importance could not be attached to the condition of the excretory organs. Preliminary examinations were imperative in each case. There should be thorough and complete elimination before commencing the reduction of the drug, after which reduction might be painlessly carried to a certain point, and all shock avoided. All this time help should be given, not as a substitute, but in the shape of a neuro-cardio-vascular support. When the drug was entirely removed, a substitute should be used, not hyoscine. The value of the non-medicinal treatment, such as massage, vibration, electricity, hydrotherapy, isolation and moral control, could not be overestimated in these cases. The value of after-treatment and the need of keeping in touch with the patients were a part of the system. Personality also entered a great deal into the question.

Dr. Frank P. Norbury, Jacksonville, Illinois, had not always had idealistic experience in the treatment of these cases. Recovery was not always smooth, and relapses were not infrequent. It was advisable to place these patients at rest in bed at once, and after perhaps two weeks the drug might be withdrawn. Often sodium bromide was useful as a substitute for the morphine, and cannabis indica was frequently of value as a stimulant. Relapse was especially frequent in neurasthenic women.

Dr. John Punton said we must give the patient to understand at the start that the physician must have his coöperation. The idiosyncrasies of patients to the drug differed, hence it was necessary to treat the patient. Hyoscine was a most valuable drug when properly used, but it was very dangerous when used promiscuously.

Dr. Albert E. Sterne, Indianapolis, agreed with the essayist in general, but did not think he laid sufficient stress on the reduction of the basis upon which the drug habit rested. One must take into account the fundamental nerve weakness. Even the physically strong might present nerve weakness. Habituation was not purely functional. There was a structural change in the nervous system, which supplied the physical basis for the condition. The use of drugs was to be deprecated. Many of the so-called abstinent symptoms were really not such symptoms. Often hyperacidity required treatment. Furthermore, every morphine habitué was a liar and absolutely untrustworthy concerning his condition.

Dr. T. B. Greenley, Kentucky, said that many morphine habitués were able to work and earn sufficient to pay for the drug consumed, but made barely a living, and could not afford to take proper treatment.

Dr. George P. Sprague, Lexington, Kentucky, was surprised that the essayist did not begin at once the reduction of the drug, as there was every reason why it should be withdrawn immediately. The patient might be taken off the drug in from five to ten days, except in, perhaps, one case in twenty. Often the patient was sustained by a minute quantity of morphine. Some patients claimed that one-eighth of a grain was satisfactory, and the reduction to that point was not objected to by them. Often it was better not to stop the drug altogether until one had reached a dosage of one-twentieth of a grain, or less.

Dr. R. E. Haughton, Richmond, Indiana, regarded this condition as a practical toxæmia affecting the cellular elements of the brain. After deciding upon the withdrawal of the drug, we must secure absolute control of the patient, in order to be successful in treatment. We must sustain the individual and at the same time secure elimination.

Dr. T. D. Crothers said a melancholy fact was the large percentage of the profession that were victims of morphine. The treatment employed must depend upon the individual. Psychotherapeutics and hydrotherapeutics were useful. Nerve rest was important. Drugs should be avoided.

Dr. Falk said that in prison practice he withdrew the drug from patients at once. The use of ergot and of chloral and bromide at night he had found was not followed by any unpleasant results.

Dr. B. F. Beebe said the removal of the drug in one week or ten days was too rapid. The patient should be built up as the drug was withdrawn.

Dr. Pope, in closing, insisted upon four to six weeks for the after-treatment, because nutrition must be improved. Treatment during convalescence was important. When the patient stopped treatment, he should be instructed to return at once if there were any unpleasant symptoms.

Effect of Direct and Indirect Violence Upon the Skull and Brain.—Dr. Albert E. Sterne, Indianapolis, Indiana, read a paper on this subject in which he presented the following summary: (1) Injuries of the skull and brain may be classed under two heads, those of impact and those of momentum, either of which may be occasioned either directly or indirectly. (2) Injuries of impact, however extensive, offer a better immediate and remote prognosis, but must be treated with as little delay as possible, and almost always surgically. (3) Injuries of momentum show graver probabilities both in the immediate and remote effects. (4) In injuries of momentum lesions through *contrecoup* are more apt to occur, with extensive damage to brain structures and often without fracture of the skull, or external wound. (5) After trauma to the skull and brain, the immediate necessity is free drainage and avoidance of intracranial pressure. (6) The possibility of fracture should ever be kept in view after injuries to the head, and scalp wounds should, if necessary, be freely enlarged to determine the wisdom of further operative interference. (7) Progressive coma, after momentum injuries, is a strict indication for operation.

A Clinical Study of the Mental Disorders of Adolescence.—Dr. Frank P. Norbury, Jacksonville, Illinois, discussed this subject under the following heads: (1) Adolescence presents a physiological study of contrasts revealed in (*a*) normal psychology of this period, (*b*) psychophysical symptomatology, and (*c*) pathological symptomatology. (2) Clinical groupings of symptoms leading to classification of the mental disorders of adolescence; dementia præcox, katanoia, hebephrenia, hysterical excitement, etc. (3) Clinical considerations of prognosis: (*a*) Evolution of mental disorders; (*b*) recoveries, complete, partial; (*c*) terminal dementia. (4) Treatment: (*a*) prophylaxis; (*b*) immediate. (5) Conclusions: (*a*) the family physician must recognize early these important mental disorders; he must coöperate with the alienist in treatment; (*b*) prompt and energetic treatment is imperative; (*c*) prognosis should be guarded.

Insanity in Relation to Obstetrics and Gynecology.—Dr. Henry F. Lewis, Chicago, contributed a paper with this title. He stated that various types of insanity might affect the pregnant or puerperal woman, or the woman suffering from pelvic disorder. There was no true puerperal insanity, however, as such. Normal pregnancy and even normal menstruation were not devoid of certain eccentricities of temper, tastes, appetites, or even morals. Some degree of mental instability must preëxist if the eccentricities were to be exaggerated into insanity. The element of heredity was a potent factor, and could be traced in about three-fourths of the cases. Authorities differed as to the estimated frequency of obstetrical insanity. McLeod's figures gave a proportion of one case to 2,000 labors. Clouston found 10 per cent. of insane women at the Edinburgh Asylum were classified as having puerperal psychoses. Lane, from observations in the Boston Insane Hospital for the past ten years, concluded that insanity associated with childbirth occurred only half as often as insanity among all women of child-bearing age. At best, one could grant to child-bearing only an exciting causal relation in the production of an outbreak of insanity. The predisposing instability of mind, often largely hereditary, awaited some awakening impulse in an acute physical or psychical disturbance. Such disturbance might be furnished by disorders of the genital organs in the performance of their normal functions. The relation of disease of the female genital organs to mental disease had long been recognized, but the intimacy of sex relation had been the subject of wide differences of opinion. A very large number of insane women were affected with pelvic disease. A considerable number of gynecologists had operated upon insane women at asylums for their genital lesions and had secured a gratifying percentage of cures and instances of improvement. Hobbs of London, Ontario, observed over a thousand insane women and found pelvic disease of sufficient moment to justify operation on account of the pelvic disease itself in 25 per cent. of these women. All his examinations were made under the influence of an anæsthetic, and suggestion was thereby eliminated. Ovarian lesions seemed to influence the mental state the most, uterine next, and vaginal the least. Neoplasms were the least prone to cause mental disorder of all the pathological conditions.

Newer Conceptions of the Management of Bright's Disease.—Dr. Alfred C. Croftan, Chicago, Illinois, considered this disease as a cardiovascular disorder of manifold origin, involving primarily the heart and arteries; secondarily, those organs chiefly supplied by end arteries, namely, the brain, the retina, and the kidneys. The degeneration of the kidneys was, therefore, a very common and important, but not a determining, feature of the disease. Bright's disease in early stages not infrequently occurred without renal involvement. Primary nephritis with the retention of excrementitious bodies might occasionally be a cause of the cardiovascular changes. This sequence of events, however, was relatively rare. The management of Bright's disease should be directed towards the prevention or removal of factors operative to affect the heart and arteries. The treatment of the nephritis was incidental, but important. The rest cure of the kidneys, diet (dangers of exclusive milk feeding), hygiene, and medicinal treatment were discussed on the basis of the above conceptions.

The Early Recognition of Important Eye Lesions by the Practitioner.—Dr. George F. Suker, Akron, Ohio, pointed out the early diagnostic eye lesions in diabetes chronic nephritis, and locomotor ataxia. Reference was made to the diagnostic conjunctival spot in cases of measles. He spoke of the frequency of mistaking glaucoma for trifacial neuralgia; also the frequency with which simple, chronic glaucoma was confounded with cataract. He emphasized the need of recognizing the eye conditions as

a factor in chorea, functional epilepsy, neurasthenia, and hysteria. The relation between gastrointestinal derangements and certain eye lesions was pointed out, and the need of a thorough ophthalmic examination in the neurotic and chlorotic patients of this character was emphasized.

The Value of the X-Ray to the General Practitioner.—Dr. James E. Coleman, Canton, Illinois, said that as the practice of medicine was still largely in the hands of the general practitioner, it made it necessary for him to improve to the greatest extent his resources for diagnosing and combating disease. *X*-ray apparatus has become a necessary adjunct. In order that it might be satisfactory, it must be first class. Every general practitioner should have one text-book on *x*-ray therapy. The mastery of the details and technique was not difficult when studied, but success depended upon a knowledge of anatomy and proper interpretation of the screen and skiagraph. Cases were cited.

Macular Atrophy of the Skin.—Dr. Edward H. Shields, Cincinnati, Ohio, said that this rare disease was first described by Jaddoson, in 1892. No other case had been reported. The author presented the following history of a case: Eighteen months ago red macular lesions were found on the legs and thighs, with no subjective symptoms. Some weeks later the patches lost redness, became softer, depressed, and the skin over the diseased area became shriveled; atrophy continued for several weeks, when the atrophic spot became soft and pale. Owing to the marked irritability of the skin, the atrophic lesions did not appear very pale immediately after the removal of the clothing, but after half an hour of absolute rest they became quite pale, resembling those of morphine. He stated that treatment was of little value, yet in due course of time the process was arrested.

Why So Many Errors in the Diagnosis of Graves' Disease?—Dr. J. H. Stealy, Freeport, Illinois, emphasized the importance of a correct nomenclature and its bearing on errors of diagnosis. He pointed out the illogical nature of the term exophthalmic goitre as applied to the symptom-complex of Graves' disease, and showed what a remarkably large number of cases of Graves' disease could be found if sought for. He discussed the percentage of symptoms, the diagnostic importance of each, and also the symptomatology.

Echinacea.—Dr. C. S. Chamberlin, Cincinnati, Ohio, made a plea for the recognition of echinacea as a valuable therapeutic agent. He gave a brief history and description of the drug, and referred to the suspicion with which the regular profession regarded remedies introduced by irregular practitioners, and their reluctance to investigate their merits. He cited brief reports of cases, illustrating the therapeutic value of the drug as an alterative and antiseptic, and its range of application.

The following papers were also read: "Pseudo-Membranous Croup," by Dr. R. E. Carlton, Latonia, Kentucky; "Bacteriology and Immunity; What It Is, What It Teaches, What It Does Not Teach," by Dr. R. E. Haughton, Richmond, Indiana; "Two Etiological Factors in Pelvic Diseases in Women, Their Prevalence and Prevention," by Dr. J. H. Firestone, Freeport, Illinois; "Prognosis," by Dr. John M. Batten, Downington, Pennsylvania.

(To be continued.)

Lumbar Puncture in Eclampsia.—Krönig reports on the effect of this procedure in three cases of eclampsia. In the first two cases it was possible to make measurements of the cerebrospinal pressure, and it was found much increased in both instances, at times being as high as five to six hundred mm. of water, whereas the normal pressure is only about 120 mm. Various amounts of cerebrospinal fluid were allowed to escape in each case, but the author does not know whether to ascribe the improvement and recovery that followed to this element of the treatment or not.—*Zentralblatt für Gynäkologie.*

AMERICAN PROCTOLOGIC SOCIETY.

Sixth Annual Meeting, Held at Atlantic City, June 8 and 9, 1904.

Dr. Wm. M. Beach, of Pittsburg, President, in the Chair.

The President's Address, upon the subject "Things of Specialism and of This Society That Make for Optimism," was an argument in support of specialism in general and of proctology in particular. He pointed out that the favorable recognition which had been accorded this specialty was largely due to this Society, and that as a direct result, though the society was only six years old, the advertising charlatan had practically disappeared. The high type of men composing the membership was alluded to, and the continued exercise of careful circumspection in admitting new members advocated.

The Surgical Treatment of Prolapse of the Rectum.—Dr. J. M. Mathews, of Louisville, Ky., reported excellent results from drawing up the colon and suturing it to the abdominal wall. He had resorted to the method in a number of cases, and believed the operation, colopexy, was worthy of more general adoption.

Treatment of Pruritus Ani with the Röntgen Rays.—Dr. J. R. Pennington, of Chicago, from an experience covering a period of several years, had reached the conclusion that the *x*-rays were valuable in certain obstinate cases in which no cause for the pruritus was discoverable, and in which the secondary changes in the parts affected were most marked. He had succeeded in a number of instances in effecting a cure after every other form of treatment had failed.

The Present Status of the Treatment of Cancer of the Rectum.—Dr. Lewis H. Adler, of Philadelphia, considered four methods of treatment: (1) The *x*-rays; (2) radium; (3) extirpation; (4) colostomy. Speaking from his own experience, he condemned both the first and second, the *x*-rays as aggravating the disease and apparently hastening death, radium as being non-effective. With reference to extirpation, he said that cancer of the rectum, at the stage usually discovered by the surgeon, was far less amenable to operative treatment than cancer occurring elsewhere; that extirpation, even when thorough, was followed by cure in only a small percentage of cases, owing frequently to prior metastasis; that the danger attending excision of growths situated above the lower two or three inches was very great; and that the results as to freedom from pain in successful cases were usually far from satisfactory. He personally had been unable to advise excision in more than 5 per cent. of cases. Colostomy the author regarded a valuable palliative operation, the patient living in comparative comfort an average of three or four years. Personally he did not advise colostomy as early now as formerly.

The Flexible Rectal Tube was condemned by Dr. S. T. Earle, of Baltimore, as impracticable and of limited utility. His investigations of the subject had led him to conclude that as ordinarily employed by nurse or patient, the instrument curled upon itself in the lower rectal chamber and very rarely entered the sigmoid. This difficulty might be overcome in a measure by attaching the nozzle of a fountain syringe to the tube and allowing enough water to enter the bowel to distend it in front of the advancing tube. In inexpert hands the instrument was capable of harm and, except in the hands of the physician himself, the writer thought it should give place to the ordinary enema nozzle and elevation of the patient's hips, by which method the same results could generally be obtained.

Polyadenomata of the Rectum.—Dr. G. B. Evans, of Dayton, O., presented a paper on this subject, in which he referred to the comparative rarity of the disease and emphasized the importance of early and complete removal of the tumors, their tendency to undergo malignant changes being the chief danger. With the more general employment of instruments of precision in rectal examinations the writer predicted that polypi would be more frequently encountered in future.

Some Observations on the Treatment of Rectal Diseases.—Dr. W. L. Dickinson, of Saginaw, Mich., spoke of the great prominence diseases of the rectum had gained in the past twenty-five years. When he was a student the entire subject was disposed of in one lecture by the professor of surgery, "piles" being the only disease alluded to. Improvements in the office treatment of these conditions were discussed at some length, the author showing that it is possible in a large number of cases to do good, thorough work without general anæsthesia and confinement of the patient to bed.

Rectal Valves, with Report of Operative Cases, was the title of an essay by Dr. L. J. Krouse, of Cincinnati. The author discussed the indications for valvotomy and endorsed it as a justifiable operation in properly selected cases, reporting a series of cases in which great and permanent benefit had followed its performance.

Treatment of Simple Rectal Fistula by Excision and Suture without Cutting the External Sphincter Muscle.—Dr. Howard A. Kelly, of Baltimore, read a paper on this subject, in which he described the technic of an operation devised by himself and successfully employed in a number of cases. The procedure was applicable only when the fistula was simple and direct, and consisted in dissecting out the tract, beginning at the external opening. The rectal orifice was then carefully excised through the wound so as to make a transverse opening parallel to the sphincter fibers. The wound was closed by interrupted silk-worm-gut or silver-wire sutures, taking care to draw the circular fibers together above and below the rectal orifice.

Sterile Water Anæsthesia in the Radical Treatment of Rectal Diseases, was the subject of a paper by Dr. S. G. Gant, of New York. (See page 691.)

Papers by Dr. Leon Straus, of St. Louis, and Dr. A. Tierlinck, of Gand, Belgium, in the absence of the authors, were read by title.

Officers.—The following officers were elected, after which the Society adjourned to meet in Pittsburg, May, 1905: *President*, Dr. J. R. Pennington, Chicago; *Vice-President*, Dr. L. H. Adler, Philadelphia; *Secretary-Treasurer*, Dr. A. B. Cooke, Nashville; *Executive Council*, Drs. W. M. Beach, Pittsburg, S. G. Gant, New York, and G. B. Evans, Dayton.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, October 10, 1904.

Dr. Thomas E. Satterthwaite, President, in the Chair.

Mosquitos, Malaria, and Yellow Fever.—Major Junius L. Powell, Surgeon, U. S. Army, who read this paper, said he would limit himself to the subject of mosquitos in their relation to malaria only. At Fort Hamilton, L. I., where he was stationed, he had made a very careful study of this subject, and had been almost forced to the conclusion, heretical though it might seem, that *Anopheles* was not the sole transmitter of the malarial parasite. Two varieties of mosquitos were very common at Fort Hamilton, namely, the ordinary Atlantic coast variety known as *Culex sollicitans*, and *Culex pungens*, and only in a single instance had he been able to discover a specimen of *Anopheles*, in spite of thorough and repeated search. Notwithstanding the absence of the *Anopheles*, fully a score of cases of malaria had developed at the garrison since the first of May of the present year. The question therefore arose, were there any other methods of conveying the malarial organism than through the medium of the mosquito? Similar observations to the above, Major Powell said, had been made at Camp McKinley and other garrisons, where malaria had developed in spite of the fact that no *Anopheles* could be discovered.

Tropical Malaria.—Dr. John V. Shoemaker of Philadelphia, presented this paper. He said he employed the term "tropical malaria" as indicative of the behavior of the plasmodium in cases occurring in the tropics. His observations were based upon fifty-three cases brought to the Medico-Chirurgical Hospital, in Philadelphia, from Cuba, Porto Rico, and various camps in this country during and immediately after the Spanish-American war. Many of these cases were of the ordinary intermittent type, but a certain number presented a more profound and unusual intoxication. Most of the cases were distinguished by the severity of the symptoms and the irregular course of the fever. All were accompanied and followed by extreme prostration. According to the histories that were obtained, they began more or less insidiously with headache, which was in some instances excessive, backache, general weakness, anorexia, and in some cases a general soreness. One patient suffered from a dull feeling at the lower border of the left rib, and pain in the lumbar region. In a number of instances, vertigo occurred. In one case it was noted that the eyes suddenly became very painful. Some patients complained of pain in the bones. In some the fever supervened without any well-marked chill; in others the chill was a prominent feature. One man suffered from a prolonged chill every day, accompanied by fever of the remittent type. Sometimes, but not always, the fever was followed by profuse sweats. One interesting case displayed a chill every morning and every afternoon for two weeks, each chill being succeeded by fever and sweats. The temperature charts departed widely from that of ordinary or benign malaria. In one case in which the initial chill was severe it had been preceded by intense pain in the head and back; the chill returned every day for three days. One patient stated that his attack began abruptly with a chill, which was repeated upon the following day. One man's illness began with a rigor which lasted for half an hour, followed by fever and profuse sweating; his headache was violent; chills occurred every other day; upon one occasion the chill lasted fully two hours. Another patient had a chill every other day, lasting an hour and a half and followed by high temperature. One man went to sleep at night with a violent headache, and awoke to find himself in a cold sweat which was followed by a chill and fever, a reversal of the ordinary succession. Another patient had a violent chill, after having been ill for four days, and subsequently suffered from a repetition of chills every day for twelve days. In many of the cases there was such a blending of succeeding paroxysms with the febrile rise and fall that the report approached that of a continued fever. Several cases were accompanied by acute bronchitis, and gastro-intestinal symptoms were marked in a considerable proportion of the patients. All experienced loss of appetite and loathing of food. As a rule, the tongue was heavily coated. Nausea and vomiting were common, and some of the men complained of abdominal pain. In some of the histories, mention was made of diarrhœa, and in others of dysentery. Gastric symptoms were prominent in some instances. In some attacks the bowels were unaffected; in others, constipation was the rule. The spleen was more or less enlarged in most of the men; in some there was tenderness over the spleen without much increase of size. In several patients, the color of the skin was noteworthy: the discoloration varied from a sallow hue to the deepest jaundice, and testified to the alteration of the hæmoglobin by the malarial parasite, and its liberation from the red cells. In many of the cases there were recurrences after a defervescence of ten days or two weeks. In numerous cases there was a decided diminution in the secretion of urine; it was high colored, contained urea, uric acid, bile-pigment, and, in some instances, albumin. In one case there was hæmaturia. In two cases the deep yellow shade of the whole body, the vomiting, and diarrhœa, were highly suggestive of yellow fever. There was no genuine black vomit, although the material ejected from the stomach was dark in color. Dr. Shoemaker said that in the treatment of these severe cases of tropical malaria, quinine was his main reliance. In the worst cases, however, the stomach was so irritable and vomiting was so incessant that the drug was not retained when given by the mouth. Under such

conditions he made use of suppositories, inserting a five or ten-grain quinine suppository into the rectum every two or three hours, according to the severity of the symptoms, and thus endeavoring to anticipate the paroxysm. In cases accompanied by constipation, small, repeated doses of calomel placed upon the tongue produced movement of the bowels, and at the same time allayed the gastric irritability. When diarrhœa was present, he combined equal quantities of quinine and salol. In some cases ipecac, in quarter-grain doses, was incorporated in the suppository, conjoined with quinine; this union lessened the irritability of the intestinal mucous membrane, and increased the secretion, and also had a sedative action upon the nervous system. When nervous symptoms were prominent, cannabis indica or the monobromate of camphor was combined with the quinine. If the bowel was irritable, he used an enema of starch water and laudanum before inserting the suppository. When the fever was high, the patient was sponged. In the worst cases it was necessary to place the patients upon a milk cases it was necessary to place the patients upon a milk diet. Notwithstanding the profound malarial intoxication of some of these cases, happily none had a fatal termination.

Is Mortality Necessarily Higher in Tropical Than in Temperate Climates?—Colonel Valery Havard, Assistant Surgeon General, U. S. Army, presented this paper. He said that while it was a fact that mortality had been and still was much higher in tropical than in temperate climates, the question arose whether this difference was due entirely to meteorological conditions, or to the violation of sanitary laws, and therefore preventable. A careful study of the statistics seemed to indicate that mortality was due to many causes, of which latitude was one, but not the only one. That mortality did not decrease with the distance from the equator could easily be shown by comparing the death rate of certain large cities; for example, St. Petersburg was 10° farther north than London, and still its death rate was considerably higher. The meteorological elements in the tropics that were capable of affecting the health were, first, great continued heat, and, second, a high degree of humidity. The death rate in Manila, although it had been largely reduced under American rule, was still about 40 per 1,000, according to the report for the year ending April, 1904. Fifty-seven per cent. of these deaths occurred in infants, most of them under one year of age, this frightful mortality being chiefly due to the careless manner in which the infants and children were brought up by their parents, suffering, as they often did, from exposure, want of proper clothing, food, and lodging. The most common cause of death in infants was convulsions: other causes were bronchitis, pronchopneumonia, diarrhœa, and inanition. In Havana, children were much better taken care of, and the infant mortality was less, comprising only one-fourth or one-fifth of the total number of deaths, which was a more favorable ratio than that of New York City. The death rate from tuberculosis was high, both in Manila and in Havana. These cities were apparently saturated with tubercle bacilli, as a result of the unsanitary conditions to which they had long been exposed. Next to tuberculosis, cholera was responsible for the greatest number of deaths in Manila. Cholera, as was well known, was a water-borne disease, and was easily preventable. Dysentery was one of the most dreaded of the endemic diseases of the tropics: in Manila it still continued its ravages among the natives, but was comparatively rare among the American and European residents. Beriberi was still common in certain parts, attacking mostly natives whose constitution was undermined. The disease would doubtless become preventable when its mode of transmission became better known. Yellow fever, once so dreaded, had been practically exterminated in Cuba. Its transmitter, the *Stegomyia fasciata*, probably did not exist very far north. Malaria was common in all warm countries, although there was probably not a single State in the Union where the *Anopheles* could not be found. The speaker said he was unable to say whether the virulent type of malaria at times met with in the tropics was due to the climate, or whether it was a fever distinct from malaria that had thus far been unrecognized. The positive results obtained by the use of mosquito bars, as well as doors and window screens, in Cuba, Italy, and the Philippines, demonstrated that malaria, whether of the mild or pernicious type, could be easily prevented. Many of the natives, however, had not yet learned how to exclude mosquitos without at the same time excluding air. Bubonic plague was not known in Cuba, and was responsible for only one death among the Americans in the Philippines. Smallpox could be prevented by vaccination in the tropics as well as in the United States, and not a single case of this disease had originated in Cuba since 1890, when vaccination became obligatory there. Cancer and pneumonia were most common in temperate climates. Diphtheria and croup were practically absent in the tropics. Colonel Havard said it appeared from his study of statistics that the death rate of the tropics was swelled by a large infant mortality, and was due to diseases that were pretty well understood and largely preventable. It was only a question of time before yellow fever would be completely eradicated from this continent, and if, as was generally believed, malaria resulted from the sting of the *Anopheles*, the reduction of that disease to a negligible quantity could be confidently looked forward to. Tuberculosis still remained as the greatest scourge, both in temperate and tropical climates, and better results probably followed its treatment in warmer than in colder climates. Mortality, as a whole, depended more upon civilization and government than upon climate.

Tropical Fruits and Tropical Diet.—By Dr. H. W. Wiley, Chief of the Bureau of Chemistry, U. S. Department of Agriculture, sent this paper, which, in Dr. Wiley's absence, was read by the Secretary. The writer stated that the question of a proper diet in the tropics was one of the greatest importance. With a change of environment, the food must also be changed. In the tropics, it should be of a less heat-forming character than that used in temperate and especially in polar regions. So far as was known, the fats and oils were the chief heat-producing foods. In this they differed from the carbohydrates, which were active both in building up tissue and in furnishing energy. In the tropics, fats should comprise only a moderate portion of the diet, and the quantity of nitrogenous food should be decreased. Nature, as a rule, furnished the food best suited for the nourishment of the people in the particular region where they lived, and in the tropics the fruits largely answered that purpose. Dr. Wiley's paper then gave a list of the more important tropical fruits, with their constituents. This showed that the cocoanut was the chief natural oily food of the tropics, while the cassava was the principal starchy food. The natural tropical food was one containing a large excess of carbohydrates, of which the sugar predominated.

Dr. N. S. Jarvis called attention to the large reduction of mortality in Cuba and the Philippines since the Spanish-American war, under the able administration of the medical officers of the U. S. Army, who had accomplished what European medical officers had failed to do in the colonial possessions of those countries. While the American medical officers had not received the honors which were usually given to men on the firing line, they had accomplished greater results than the men with the rifle.

Dr. Shoemaker, in reply to a question as to whether he had tried the hypodermic method of administering quinine in cases in which its administration by the stomach was deemed inadvisable on account of gastric irritability, said that the method had been given a trial in some of the cases he had referred to in his paper, but the injections gave rise to so much inflammatory reaction on account of the debilitated condition of the patients that it was abandoned. The use of quinine suppositories was found much more efficacious.

Colonel Havard, in closing the discussion, said that while *Anopheles* was rarely met in comparison with *Culex sollicitans* and *C. pungens*, even a single specimen of *Anopheles* might do a lot of mischief before it was discovered. Furthermore, in order to transmit malaria, the *Anopheles* must first become infected, and, while Major Powell, at Fort Hamilton, had observed malaria without the presence of this mosquito, the speaker said he had been in localities where the members of this species were comparatively numerous, but where there was no malaria.

College of Physicians of Philadelphia; Section on General Medicine.

At a stated meeting held October 10, Dr. Joseph Sailer reported "A Case of Miliary Tuberculosis Which Gave a Positive Widal Reaction." The patient was an intelligent colored man, 29 years old, without a previous history of typhoid fever, who presented symptoms of thoracic and abdominal tuberculosis. At first there was no reaction to the agglutination-test, although subsequently this reaction was obtained with the blood-serum and the serous fluid withdrawn from the abdomen and the chest. Death took place and examination disclosed the lesions of tuberculosis, but none indicative of typhoid fever, although inadvertently cultures were not made from the spleen.

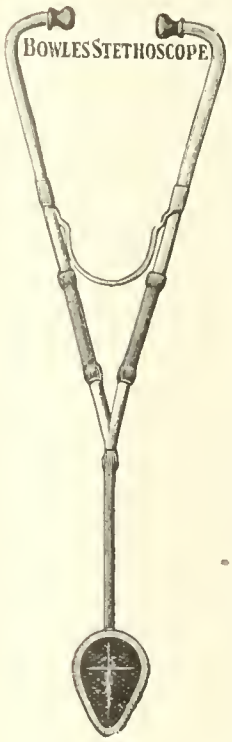
Dr. J. H. Musser read "A Note on Chronic Parotitis," reporting a series of cases in elderly and middle-aged individuals, in some of which repeated attacks of inflammation of the parotid gland and sometimes also of other salivary glands occurred, while in others persistent swelling of the gland followed an attack of acute inflammation. Drs. M. H. Fussell and C. A. Fife reported "A Case of Uncinariasis," and they exhibited specimens of the uncinaria. The patient was a young white man of English extraction, born in the West Indies, who had worked on various plantations as a millwright. Presenting himself with symptoms of marked anæmia of obscure origin, examination of the intestinal discharges disclosed the presence of ova and mature uncinariæ, together with the tricocephalus dispar and lumbricoides. The number of eosinophile cells in the blood was increased. Under vigorous treatment with thymol both the ova and the parasites disappeared from the stools, the anæmia subsided, and improvement in the general condition took place.

Caesarean Section and Serious Dystocia Following Ventrofixation and Suspension.—Frank W. Lynch thinks that it should be inquired whether operations likely to result in fixation of the uterus to the anterior abdominal wall are ever justifiable during the childbearing period. The untoward results following ventrofixation clearly indicate that the operation should be abandoned, while the few cases in which unintentional fixation has followed supposed suspension of the uterus, render it questionable whether even this more conservative operation should be employed. The writer declares that he is inclined to take the ground that neither procedure is justifiable until after the menopause, as it does not seem proper to undertake an operation for the cure of a condition which does not threaten the life of the patient and merely exposes her to a certain amount of discomfort, when it is known that it may give rise to most serious dystocia should she become pregnant. Which will prove the most suitable operation for the cure of displacements of the uterus during the childbearing period, the writer states, cannot yet be definitely predicted, although he believes that some of the procedures which aim to maintain the organ in position by shortening the round and the utero-sacral ligaments, will eventually prove to be the operation of choice. It is possible that Alexander's operation may prove the ideal procedure when the uterus is movable; but when it is adherent the abdomen must be opened, in order to free it, and under such circumstances some intra-abdominal methods of shortening the ligaments would appear most rational.—*Bulletin of The Johns Hopkins Hospital.*

New Instruments.

A NEW PATTERN OF BOWLES' STETHOSCOPE.

By R. C. M. BOWLES., C.E.,
BROOKLINE, MASS.



At present the Bowles Stethoscope is manufactured in two sizes, one of 2-inch diameter and one of 1⅜-inch. The larger being used when examining a substantially large area, the latter for smaller areas, such as above the clavicle, the apices, intercostal spaces, etc. In the latter cases, the larger is unavailable on account of its diameter, and the smaller not entirely satisfactory on account of its decreased vibratory surface.

To meet these conditions at least partially, I have constructed an instrument of pear or flat-iron shape of diaphragm, whereby is obtained the maximum vibration of the larger style of stethoscope, with the adaptability of the smaller instrument; also the volume of sound can be varied at the will of the operator, according to the degree of contact with the body.

This instrument is made by Geo. P. Pilling & Son, Philadelphia.

Uncinariasis in the Mountains of North Carolina.—W. P. Ivey thinks that great care should be taken to use the technical term, and to avoid the term hookworm, or hookworm disease. He gives the history of various cases which have come under his observation. In the first case he mentions the symptoms were anæmia, œdema, severe headache, and pain in the stomach. The color of the fæces was decidedly reddish, showing plainly the presence of blood. The thymol treatment was given, and plenty of small, threadlike creatures were found, about the size of a No. 10 thread. Another patient was so waterlogged that she could hardly breathe, and could not sleep in the recumbent position. The next night after the thymol treatment she was much improved, and the second night she slept naturally as well as usual. One patient was afflicted with femoral phlebitis, with a very large, tender and painful leg. The writer has recently examined twenty suspected cases, and has found the disease in every case. These cases have been in the same county, which is not a sand district, but is right in the mountains, with a clay soil, with here and there a mixture of sand and clay on a clay subsoil. One of the most common complaints for which these patients seek aid is a supposed heart disease. Next to the cardiac symptoms in frequency stand disorders of menstruation, in some cases amenorrhœa, in others menorrhagia. All of these cases of uncinariasis are much benefited by the treatment for anæmia alone, but the benefit it not lasting. The writer declares that he knows of no disease of like importance that is so quickly and certainly relieved by treatment as the disease under consideration. But reinfection often takes place quickly. He believes that most of the cases, especially among children, ought to be given a course of thymol at least every three months. There must be preventive as well as curative treatment. The writer concludes by emphasizing the importance of recognizing the disease and giving some of its effects. It causes death. It makes mental underlings. It makes physical dwarfs. It curtails producing power. It steals dollars from our wealth. —*Charlotte Medical Journal.*

A Radical Operation for Malignant Neoplasm of the Urinary Bladder.—Albert Ashton Berg describes such an intraperitoneal operation which offers certain advantages, as follows: It affords the freest access of any to carcinoma of the posterior wall and base of the bladder. It is the only method by which the indurated lymphatics and glands along the internal iliac artery can be removed. It permits us to remove the ureter when diseased, and at once to reimplant it into the bladder or into the opposite ureter. It allows of accurate suture of the defect created in the bladder wall. It permits of excellent drainage below. The objections may be raised that we expose the patient to greater and graver risks of infection than by the extraperitoneal method of resection. This cannot be denied; but, as it is impossible to remove the glands and lymphatics by the extraperitoneal method, we must either give up all attempts at radical cure of vesical carcinoma or resort to the intraperitoneal method as outlined. The danger of infection is reduced to the minimum and very little blood is lost during the operation. The dissection of the pelvic floor is not an easy one. The writer has practised this operation upon two patients in the past year.—*Annals of Surgery.*

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended October 22, 1904.

CANCER OF THE LARYNX.*

By SIR FELIX SEMON, C.V.O., M.D., Berlin, F.R.C.P., London.
LONDON
PHYSICIAN EXTRAORDINARY TO HIS MAJESTY THE KING.

Mr. President and Gentlemen.—The keynote of the observations which I shall have the honor of addressing to you was struck in a discussion on malignant disease of the larynx at the meeting of the American Laryngological Association in 1902, when Dr. Bryson Delavan stated that it was time "that the discussion of these subjects upon theoretical grounds should give place to careful studies of what was actually being accomplished by practical men." Self-understood as this desideratum might seem to be, I am afraid that it has been far from being acted upon universally. Indeed, the future historian of the progress of laryngology in our own times will have rather a strange tale to tell, not merely of the diversities of opinion still existing in the different civilized countries in the year 1904 as to diagnosis and treatment of malignant disease of the larynx, but even more of the disregard of the practical results obtained in one country, by eminent specialists practising in other parts of the world. It is this aspect of the question with which I shall deal in the course of my remarks. At the same time I do so, I confess, in some fear and trembling. It is not only because I speak under the eagle eye of my friend Dr. Jonathan Wright, the implacable enemy of medical controversy in any shape or form, but more still because I feel that it might seem ungracious that, in return for the magnificent hospitality of which I have been, and still am, the recipient in this country, I should criticise, as will be my duty, the emphatic views recently expressed on diagnosis and treatment of cancer of the larynx by an eminent American laryngologist, my old friend Dr. John Mackenzie, of Baltimore. But after mature consideration, I have come to the conclusion that I can only do full justice to the task you have so kindly confided to me by endeavoring in the frankest possible manner to show the untenability of his objections to the methods by which British laryngologists have obtained very satisfactory results in dealing with this scourge of mankind. This may be the only occasion in my life on which I shall have the privilege of addressing on this subject—which I have at heart and on which I have worked for fully twenty years—a meeting of American experts, and I strongly feel that a scientific discussion on such a topic ought after all not to be of the nature of a mutual eulogium, but an earnest endeavor to clear the atmosphere and to let the better cause conquer.

It is a matter of history that the case of the late German Emperor represents the turning point of modern knowledge of cancer of the larynx. Until then that knowledge had been sadly incomplete and unsatisfactory. Very little was known about the early symptoms and early laryngoscopic appearance of the disease and as a rule its existence was only recognized when it was in an advanced stage. Up to 1878 many cases were in such circumstances treated by thyrotomy, an operation which, though positively ideal in early stages, is quite insufficient, as we now know, when the disease is more advanced. The results were naturally disastrous, and led, after Paul Bruns' sweeping condemnation in 1878,[1] to almost complete abandonment for a time of thyrotomy in malignant disease of the larynx. The more severe forms of radical operation—total and hemi-laryngectomy, enthusiastically welcomed when first introduced, did not at once justify the hopes which had been raised, and in the early eighties of the last century the outlook for the unfortunate patient afflicted with laryngeal cancer was grave in the extreme.

Such is the barest outline of the state of matters before 1887. I have on more than one previous occasion[2] insisted on the necessity of every laryngologist being thoroughly acquainted with these historical facts, because it is only from their knowledge that the present state of matters and the untenability of some of the objections raised against modern thyrotomy can be fully understood. For my purpose to-day it must suffice to simply remind you of the facts just enumerated and to refer those who wish for fuller information to previous publications of mine in which these questions have been treated at greater length.[3] It is true that no sensational incident, such as the sad illness of the Emperor Frederick, was required to induce larnygologists and surgeons to try to improve from both the diagnostic and the therapeutic points of view the unsatisfactory state of matters just described. Already in 1886 I had, when bringing the well-known case of the late Mr. Montagu Williams before the Clinical Society of London, drawn attention to several so far unknown, or, at any rate, undescribed laryngoscopic signs, which had enabled me in various cases to diagnose laryngeal cancer at an earlier period than was at that time usual. Again, my late friend, Professor Eugen Hahn, of Berlin, had already, previous to the illness of the then Crown Prince, materially improved the technique, especially of partial extirpation of the larynx and had by the invention of his excellent sponge cannula greatly diminished the mortality previously resulting from septic infection of the lower air passages during and after operation. But although these and similar studies had done pioneer work for a better understanding and more efficient treatment of cancer of the larynx, they had remained isolated attempts, and there can be no

*An address delivered before the Laryngological Section of the New York Academy of Medicine on Nov. 2, 1904.

doubt that the sympathetic interest with which the whole world followed the melancholy course of the Emperor Frederick's illness gave a sudden and universal impetus towards a closer study and better understanding of that formidable disease. First came the revival of the deplorable doctrine of the late Mr. Lennox Browne[4]—viz., that benign laryngeal growths were specially liable to undergo malignant degeneration after intralaryngeal operation. This was followed by the publication of my "Collective Investigation,"[5] undertaken with the help of most of the prominent laryngologists of the world, to test the truth of this assertion. The material thus collected enabled me not only to show the complete want of foundation of Mr. Browne's contention, but also to establish more definitely than had hitherto been done the differential diagnosis between benign and the early stages of malignant neoplasms of the larynx and to discuss fully the position and relative importance of the microscopic examination of intralaryngeally removed fragments of new growths for the differential diagnosis between the benign and malignant forms.

Before the report of the "Collective Investigation," which was published in installments, had been concluded, Professor Bernhard Fraenkel, of Berlin, published his remarkable paper, "Laryngeal Cancer, its Diagnosis and Treatment,"[6] in which, besides studying the histological characteristics of laryngeal cancer, he advocated anew in suitable cases the treatment by intralaryngeal operation which he had first proposed in 1886. In reply, I lost no time in urging in the concluding chapter of the "Collective Investigation" some of the objections which seemed to me obvious against adopting intralaryngeal instrumentation as a suitable means of combating laryngeal cancer. About the same time Mr. H. T. Butlin[7] inaugurated a new era in the treatment of intrinsic cancer of the larynx by showing that owing to our diagnostic progress it was possible to obtain the same results in early cases by thyrotomy, which had previously been believed to be unobtainable by anything short of hemi-laryngectomy. From this time onwards the remarkable national cleavage took place which characterizes our present situation. Previous to the Emperor's illness, however imperfect and unsatisfactory our knowledge of laryngeal cancer may have been, there had at any rate been no national differences, and the opinions with regard to diagnosis and treatment which dominated our actions were, whether right or wrong, entertained by the whole laryngological world. From 1889 all this changed. A number of German laryngologists, headed by Jurasz[8] and following Fraenkel's lead, advocated, and still advocate, intralaryngeal operations in apparently suitable cases of malignant disease of the larynx. They have found allies in France, in Spain, and in America, whilst, apart from myself, the employment of intralaryngeal surgery in cases of malignant disease of the larynx has been deprecated by Schrötter, Chiari, and Paul Bruns. On the other hand, my own statements concerning the diagnostic importance of some of the early signs of laryngeal cancer have met, I am afraid, with but little attention in other countries besides Great Britain and, similarly, it is astonishing to observe how little impression the reports of British successes obtained by thyrotomy in suitable cases seem to have made upon the minds of operators on the continent of Europe and in America.

In 1900 Dr. John Mackenzie read at the meeting of the American Laryngological Association a paper entitled "A Plea for the Early Naked-eye Diagnosis and Removal of the Entire Organ, with a Neighboring Area of Possible Lymphatic Infection in Cancer of the Larynx." The contentions of this remarkable paper, with but few exceptions, run straight against all established teaching. The author demands naked-eye diagnosis of malignant disease of the larynx in its early stages to the complete exclusion of the intralaryngeal removal of a fragment for the purposes of microscopical examination. The latter he rejects *in toto,* and urges against its employment that the removal of tissues for examination subjects the patient to the dangers of auto-infection at the point of incision and to metastasis elsewhere, that it stimulates the local growth of cancer, and that the method is often inconclusive, misleading, and sometimes practically impossible. In the further course of his observations he emphatically condemns thyrotomy, and his teaching culminates in the statement that there was only one rational method, in the majority of cases at least, of dealing with cancer of the larynx: "Early total extirpation of the entire organ with its tributary lymphatics and glands, *whether the latter be apparently diseased or not,* is the only possible safeguard against local recurrence or metastasis." When I first read this paper I was not inclined to take it seriously. Throughout it substitutes theory for practice to such a degree, threatens hypothetical dangers which experience has shown practically to be non-existent, totally disregards the actual results obtained by trustworthy observers, and indiscriminately demands extreme measures where experience has shown milder ones to suffice, that I considered a detailed refutation unnecessary, and therefore referred to it in a chaffing spirit in the course of some lectures I delivered in 1901.[9] But, to my regret, the matter has not ended there. In 1902, Dr. Mackenzie, in a further discussion on cancer of the larynx, which took place at the meeting of the American Laryngological Association, declared that he abided by his views, and since then I have been credibly informed that these views have exercised a perturbing influence upon not a few minds on this side of the Atlantic. A proof of this appears to me the surprising scarcity of contributions from the United States confirming the favorable results we have obtained in Great Britain by thyrotomy. In these circumstances the opportunity offered through your kind invitation—viz., to investigate the correctness of Dr. Mackenzie's contentions and to try to bring about a more satisfactory state of matters—was extremely welcome to me. I will do my best to do justice to my task, but the subject is too large and the number of questions involved is too considerable that I could in the limited space of an address critically analyze every sentence to which I take exception. I shall, therefore, content myself with discussing the four most important of Dr. Mackenzie's assertions only. These are the following: (1) That the naked-eye method of diagnosis is a comparatively neglected method; (2) that the microscopical examination of a fragment intralaryngeally removed is

to be totally rejected; (3) that early total extirpation of the entire organ with its tributary lymphatics and glands, whether the latter be apparently diseased or not, is the only possible safeguard against local recurrence or metastasis; and (4) that thyrotomy is not up-to-date surgery, is in direct defiance of the rules that should govern us in the treatment of laryngeal cancer, and is a reversion to, and a resurrection of, a method of procedure that was discredited and abandoned half a century ago.

1. According to Dr. Mackenzie the naked-eye diagnosis is a comparatively neglected method. What is the real state of this question? In the introduction I have referred to my endeavors to promote the knowledge of the subjective signs and laryngoscopic appearances of the early stages of malignant disease of the larynx. Having in 1886[10] and 1888[11] enumerated in two communications of mine some of these signs I reverted to the subject at greater length in the "Collective Investigation" I undertook in 1888 and devoted an entire chapter of my report to a systematic description of the minute details which in a number of cases had enabled me to diagnose laryngeal cancer at a comparatively early period. This description has, so far as I know, remained up to this moment the last word on the subject. I am not aware that one single trustworthy sign has been added to those I enumerated in that chapter, and these signs have continued to enable me, and those who trusted my statements, to arrive at an early diagnosis in most of the cases which have since come under our observation. At the same time I have been particularly careful not to over-state my case nor to assert that any one of these signs, or even several taken in conjunction, could, in all cases, infallibly establish the diagnosis.[12] When I returned eight years afterwards to this question[13] I stated, even more emphatically than I had done in 1888, verbatim as follows: "Unfortunately, with the only exception of those cases in which it is possible to intralaryngeally remove a fragment of the new growth and to establish its epitheliomatous nature by the help of the microscope, *not one single sign* in the early stages of malignant neoplasm of the larynx is in itself so characteristic that it establishes with absolute certainty the malignant nature of the formation. The contour, the seat, the condition of the surface, the color of the new growth itself, the condition of the neighborhood, the mobility of the vocal cord, the age of the patient, other subjective symptoms, they all may and will *assist* the experienced eye in making the diagnosis, particularly when several of them *jointly* raise such suspicion, but all of them are not *absolutely* characteristic in the earliest stages, and the possibility of a mistake is not excluded in some less characteristic cases." Butlin, too, has correctly characterized the situation when he said in his introductory paper on the occasion of a discussion on the early radical treatment of laryngeal cancer,[14] that "we were still in this position, and were likely to remain in it for a good many years to come, that we must admit that there are three classes of cases: the first, in which anyone and everyone can make the diagnosis; the second, in which the better instructed or more experienced make it, and others do not; and the third class, in which the conditions are so obscure that no one can make the diagnosis, unless the larynx is opened, and in some of which it is even then difficult to be sure of the nature of the disease."

That, gentlemen, is, I maintain, a true description of the present state of matters. However much we all desire—and I do not yield to Dr. Mackenzie in that respect—further to advance our clinical knowledge of the early stages of laryngeal cancer, we have not made diagnostic progress since 1888. Although, no doubt, in the great majority of cases an experienced observer will make the correct diagnosis of intrinsic cancer of the larynx in its early stages from clinical signs alone, the possibility of occasional errors is anything but excluded. They have occurred in the practice of other experienced observers, and they have occurred in my own. And what is most important in view of Dr. Mackenzie's light-hearted advice—viz., to perform extirpation of the whole larynx with its tributary lymphatics and glands on the strength of naked-eye diagnosis alone is the fact noticed by others[15] as well as by myself, that when an error in diagnosis is committed it is more commonly on the side of regarding an innocent growth as a malignant one than a malignant growth as an innocent one. Let me illustrate this from my own experience. I have always considered it my duty to put my diagnostic mistakes on record to serve as a warning to others. Now, once only in my life, so far as I know, have I at first considered a growth which ultimately turned out to be a malignant one to be innocent. This was the case which Mr. S. G. Shattock and I described in 1891 and 1893 as an "Anomalous Tumor of the Larynx" in the Transactions of the Pathological Society of London. On the other hand, I have in two cases performed thyrotomy in elderly persons for an apparent epithelioma, whilst in reality the affection was papillomatous.[16] In one case I have been not a little surprised when a tumor, which I had believed to be carcinomatous, turned out to be tuberculous;[17] in two cases I have operated without being absolutely certain of the nature of the tumor with which I had to deal. In one of these cases the disease was indeed found to be malignant;[18] in the other one, however, even after opening the larynx, inspecting the ulcerating growth in its entirety, and having a microscopic examination made by Mr. Shattock whilst the patient was kept under the anæsthetic, it was impossible to decide there and then whether the neoplasm was tuberculous or malignant. I therefore operated as if the case had been a malignant one. Fuller microscopic examination, however, proved it to have been tuberculous.[19] In one case which I saw together with Mr. Butlin,[20] and in which he subsequently performed an external operation, it was found that an apparently malignant growth was in reality a leucoma, and in another case, also seen in consultation with Mr. Butlin, it was found, when he opened the larynx, that what we had feared to be a malignant growth was in reality a simple extravazation of blood into and around a vocal cord.[21] Thus out of eight doubtful cases in one case only did I regard a malignant growth as an innocent one, whilst in seven cases I committed the opposite error! In other words, if I had proceeded on the lines of Dr. Mackenzie's advice I should, in my own practice alone, have mutilated on the strength of a false diagnosis four patients for life, provided they had survived the operation. I shall return to that aspect

of the question further on. In the present connection, speaking on the strength of large personal experience, I only wish to say that I maintain most strongly that our clinical knowledge of these stages is not yet perfect and that occasional diagnostic mistakes are unavoidable. Dr. Mackenzie himself admits that "there is unfortunately no solitary unequivocal symptom or laryngoscopic sign of cancer," and seems to allow that "after weighing carefully all the facts of the case in our possession a reasonable doubt may remain as to the diagnosis." Just so; but what is the logical conclusion, gentlemen, to which all the foregoing drives us? Surely that it is the positive and imperative duty of every observer to resort to *every* method of diagnosis that could possibly help him in establishing a certain diagnosis before radical operation of any kind is performed. Such a method the great majority of us are convinced we possess in the intralaryngeal removal, whenever possible, of a fragment of a suspected growth for microscopic examination, duly keeping before our minds that this method, like most other human methods, is anything but infallible and must be used with discretion and discrimination. But to this Dr. Mackenzie says: "In the face of all authority to the contrary," emphatically "No."

2. Here we come to the second of his contentions—viz., to the total rejection of the microscope as a diagnostic help in cases of suspected laryngeal growth. His reasons for opposing intralaryngeal removal of a piece for microscopic examination are that such removal "subjects the patient at once to the dangers of auto-infection at the point of incision and to metastasis elsewhere, that it stimulates the local growth of cancer, and that the method is often inconclusive, misleading, and sometimes practically impossible." The first of these statements he supports in his next sentences, by saying that "the moment the continuity of a growth is broken, in that very moment the pathway is opened for self-poisoning," and that cancer being an infectious process "incision through the cancerous mass opens up at once a broad avenue for auto-inoculation." I need not say that the second of these statements is in no sense a proof of the first; it is merely a repetition in other words. The occurrence of auto-infection in cancer of the larynx is an event of the greatest possible rarity. There are, so far as I know, only three authenticated cases of this kind on record. Two were reported by Dr. David Newman, of Glasgow, in a discussion on cancer, published in the *Glasgow Medical Journal*, 1886, p. 94, and in a discussion in the Clinical Society of London, published in the *British Medical Journal* of January 19, 1889. The third was published by Mr. Shattock and myself in 1888, when we showed before the Pathological Society of London a specimen of a case of epithelioma of the right half of the larynx in which an epithelial insula existed on the middle of the left vocal cord, opposite the primary focus. We made the following remarks on this part of the case:[22] "Lastly, as to the isolated growth on the left vocal cord. Is this due to contact or to metastasis? Infection by contact is a question which is *sub judice*, and it is difficult by clinical observation only (as in so many other cases) to arrive at any indisputable conclusion: the direct proof must be delegated to experience. There is no theoretical reason, however, why contact-carcinoma should not occur where the surface opposite to the primary growth is excoriated or ulcerated, as might arise from its contact with decomposing cancerous discharge; for as the secondary glandular growths in carcinoma arise from the direct transference of elements from the primary tumor, there seems no reason why the direct implantation of infective epithelium to a granulating surface might not lead to the growth of a second tumor as well, seeing also that the grafting of normal epidermis is so readily effected on a similar surface. That cancer might be communicated to an intact epithelial surface is also conceivable, though in either case it might be held in argument that the spot opposite to the primary tumor was prepared only by the ensuing inflammation to become cancerous, for the same general reason which lay at the bottom of the original disease."

From this quotation it will be seen that I fully admit the possibility of auto-infection in laryngeal cancer, particularly when the surface opposite to an ulcerating new growth should have lost its covering epithelium. But when this theoretical possibility has been admitted and when the practical question is now asked: How often has such inoculation been actually observed? I am happily in the position to state that, so far as my literary knowledge goes, the three cases just mentioned are the only ones ever recorded as examples of local auto-infection in laryngeal cancer. And mark you, gentlemen, this refers not only to cases in which the surface of the laryngeal growth has been broken by the *surgeon's* instrument, but to the infinitely larger number of cases in which, without any surgical interference, the growth in the natural course of events has ultimately broken down *spontaneously*, offering the greatest possible opportunities for local auto-infection. What is quite beyond dispute is, that not one single case exists in laryngological literature in which local auto-infection has been described as having been due to intralaryngeal surgical interference. Seeing the enormous number of cases in which during the last forty years fragments of growth have been intralaryngeally removed for purposes of microscopic examination, this one fact suffices for me, and, I venture to think, will suffice for most men of a practical turn of mind, to dismiss Dr. Mackenzie's alarming assertion as too theoretical to come within the range of practical politics.

Exactly the same applies with regard to the next theoretical danger with which he threatens us. He says that probatory intralaryngeal removal of a fragment subjects the patient to metastasis elsewhere. I wish he had somewhat more definitely stated what he means by the word "metastasis" when used in this connection. Does it imply that through the instrumental interference in the larynx, torn-away particles of growth might penetrate into the bronchial tubes or lungs, or, having been coughed up, be swallowed, enter the œsophagus or the stomach, and set up secondary tumors in these parts? Or is it meant in the sense that the circulation being quickened by the local injury done to the larynx by application of forceps or similar instruments, infectious elements were likely to reach distant parts of the body by way of the circulation? Or, thirdly, is it intended to say that by removing a fragment one might stimulate the local growth of cancer, and

thereby accelerate the ordinary process of metastasis through the lymphatic channels, which, in the ordinary course of events, would probably have spontaneously taken place at a later period? As the paper does not contain any reply to these questions I must consider every one of them.

All three contingencies just named must, of course, be admitted as theoretical possibilities. But here again practical experience comes to our aid and enables us to ask the question: Where and when have the first two of these theoretical possibilities ever become real facts? The production of a secondary growth in the air- or food-passages by means of implantation of a torn-off fragment could, of course, only be interpreted as auto-inoculation in a more distant region. Where is one single proof to be found in laryngological literature that such a case has ever been observed? I know of none, and here again, gentlemen, I beg you to remember how frequently these exploratory removals have been performed during the last 40 years and how certain it would have been, seeing the conscientiousness of our profession, that some of those, at any rate, to whom such an exceptional misfortune had occurred would have considered it their duty to put it on record. The same obtains of dissemination by means of the circulation. I have just had the privilege of looking through the manuscript of a monograph on laryngeal cancer from the pen of Mr. Philip R. W. de Santi, which will soon be published, and from which the author has allowed me to quote the following fact. He has been able to collect altogether hardly 20 cases in the whole laryngological literature in which dissemination by means of the circulation has taken place. Considering that already at the time of the "Collective Investigation," that is to say, in 1888, no less than 1,550 cases of malignant disease of the larynx were on record, the total number of the cases reported at present must be, at the most modest computation, between 3,000 and 4,000, very likely more than that. Yet in less than 1 per cent. of all these cases has dissemination been observed. What makes the argument even more forcible are the following two facts: In the first place, in the majority of the cases of dissemination through the circulation collected by Mr. de Santi no operation had ever been performed. Secondly, if through the breaking of the continuity of the growth the pathway had been opened for self-poisoning one would naturally anticipate that the result of such metastasis or dissemination should occur in those organs, the blood supply of which was intimately correlated with that of the larynx—viz., in the respiratory passages. From Mr. de Santi's collection, however, it is incontestable that in the few cases of dissemination that have ever been reported the abdominal viscera were fully twice as often affected as the lungs. In view of these actual facts I refuse to be frightened by the two first of the possible contingencies dealing with "metastasis elsewhere" with which Dr. Mackenzie threatens us. He would, however, be on more justly debatable ground if he had used the word "metastasis" in that sense, that by removing a fragment one might stimulate the local growth of the cancer and thereby accelerate that process of metastasis through the lymphatic channels, which, in the ordinary course of events, would probably have taken place spontaneously at a later period. It will be best to discuss this question in connection with the second objection raised by Dr. Mackenzie against the probatory intra-laryngeal removal of a fragment of a suspicious growth—viz., the fear that by irritating the growth through partial removal the rapidity of the local progress might be increased. This fear is, of course, no new one. Already in the last chapter of the "Collective Investigation" the question was discussed at considerable length. Dr. Newman, of Glasgow, had described two cases, in one of which 10 days and in the other 17 days after the probatory intralaryngeal removal enlargement of a cervical gland was detected on the corresponding side of the neck, whilst no such enlargement had previously existed.[23] These two cases have, so far as I know, remained solitary. Nevertheless, the actuality of such an occurrence having been shown, it is the less permissible to leave it out of consideration because Newman's observations are certainly in accordance with the common surgical experience that after incomplete extirpation of cancer in other parts of the body the rate of growth of the remaining part usually quickens. Personally I am under the impression—for it is no more than an impression—that in a few of my own cases after probatory intralaryngeal removal of fragments the neoplasm seemed to increase in size somewhat more rapidly than before. I am therefore quite ready to accord a respectful reception to this argument of Dr. Mackenzie's.

But here, again, practical experience helps us in refuting this plea. I can hardly imagine that nowadays one single laryngologist should when meeting with a suspicious laryngeal growth pounce at once upon removal of a piece for microscopic examination and should when this examination had corroborated his clinical fears fold his hands in his lap and tell his patient with a regretful shrug of his shoulders that there could unfortunately be no doubt that he suffered from cancer and that the little intralaryngeal operation meant "the beginning of the end." Surely the proper attitude of a practical man when he discovers a suspicious growth in the larynx is to tell his patient that an operation would probably be required in any case and that it was of the greatest importance to remove if possible a small fragment from within in order to decide whether the operation could be completed by intralaryngeal means or whether immediate external operation was required. Should the patient under such circumstances refuse to consent to any external operation I should consider it my duty to fully explain the situation either to him, or to his family, or to his usual medical adviser. (No rule applicable to all cases can be laid down as I know from large personal experience.) Should he even then persist in his refusal I should certainly not proceed to intralaryngeal instrumentation as this could only do good in the event of the growth proving to be innocent, but might expose the operator, if unfortunately the microscope proved malignancy, to all sorts of recrimination. This practical attitude, which was first recommended by Dr. Newman, does justice, I venture to think, to the interests of the patient as well as to the conscience of the medical attendant. As a matter of fact, I have found that in exceedingly few cases only will external operation be absolutely rejected when the situation is clearly although kind-

ly explained to the patient. Seeing that the microscopist's opinion may be expected within a few days from the performance of the intralaryngeal removal, I feel sure that in cases of intrinsic laryngeal cancer the danger of metastasis occuring within that interval is so exceedingly remote that it need not be taken into serious consideration. The whole question is, in fact, whether the practical advantage to be gained is outweighed or not by the theoretical dangers to which the little intralaryngeal operation exposes the patient. Seeing the help that the microscope has so often given me in difficult cases of this kind I personally have no hesitation in following my great teacher's, the late Professor Traube's, principle, that when one is confronted with two evils one ought to select the smaller. In other words, I am absolutely in favor of microscopic examination whenever this is possible.

But Dr. Mackenzie says, thirdly, that "the method is often inconclusive, misleading, and sometimes practically impossible." Here I must again refer to the "Collective Investigation" and express my regret that our author should have so entirely disregarded the lessons taught therein. What I particularly object to in his statement is the use of the word "often." That *occasionally* microscopic examination of an intralaryngeally removed fragment might be inconclusive and misleading is, of course, known to every laryngologist in the world. The shortcoming may be due to the fact that a non-characteristic piece of the growth had been removed or that the latter was a composite one and that the fragment caught in the branches of the forceps happened to be of a nondescript or even apparently innocent character. Occasional errors in such circumstances are, of course, unavoidable. Again, that in some cases it is practically impossible to remove a piece for microscopic examination must also be freely admitted. But is a valuable method to be altogether rejected because in some cases it is inconclusive and misleading and because in others it cannot be employed? That means rushing into indefensible extremes. We possess so few methods absolutely infallible in our art that it appears to me positively unpardonable if we omit to avail ourselves of a method of the greatest value in a good many cases for no other reason than that it was not infallible in all and I may, if the defects of the microscope are emphasized, perhaps be allowed to gently remind its opponents of the instances in which its evidence upsets the most cocksure clinical diagnosis. Amongst my own diagnostic errors, to which I referred in a previous part of this address, is the case which last year I reported at length at Swansea. In that case two distinguished laryngologists had not the least doubt that the growth was of a malignant nature, nor did this seem doubtful when the larynx had been opened and the growth removed by thyrotomy.[24] The pathologist's verdict, however, was: innocent papilloma. I was not at all inclined to credit this at the time and the less so when within a year recurrence took place. The patient was again seen by two experienced laryngologists who felt sure that the disease was malignant. He refused renewed operation and lives now, I have just ascertained, two years after the first operation, in perfect health. Such a case teaches humility. Another instance of a similar kind just comes under my notice, whilst I am preparing this address. It has been described by Dr. Garel of Lyons, in the *Annales des Maladies de l'Oreille et du Larynx* (November, 1903). In this case the patient was a girl, aged 18 years, who suffered from a growth on the left vocal cord. A piece was intralaryngeally removed and the pathologist diagnosed cancer. This was disbelieved on account of the youthful age of the patient and no radical operation was performed. The patient succumbed to her disease, which later clinically proved to be undoubtedly cancerous, within two years from the beginning of the illness, and Dr. Garel, in his concluding remarks, frankly expresses his regret that he should have been misled by the clinical experience having been at cross-purposes with histological evidence. Cases like the two just mentioned are so eloquent in the lessons they teach that comment is superfluous. Within the limits of this address I cannot enter more fully upon this question. It has been thoroughly threshed out in the "Collective Investigation" and its result has been summarized in the following conclusions, which I translate verbatim:—

Microscopic investigation of intralaryngeally removed fragments in cases of doubtful laryngeal neoplasms is a valuable, but not infallible, help to clinical diagnosis. It ought to be used in all cases in which it is possible. This is by no means always the case, inasmuch as in cases of sub-mucous infiltrating cancer, intralaryngeal removal of fragments is impossible. If such removal is available one ought never to forget: (1) that it is by no means certain that the examination may at all yield results characteristic of any definite form of tumor; (2) that even when the examination yields apparently characteristic results the possibility must be kept in view that we have to do with a mixed form of new growth. This is particularly important in cases in which the tumor is clinically suspicious, and in which the microscope apparently proves its benignancy. But the reverse is also possible, as shown by a case of Schmiegelow's. It will therefore be always desirable to transfer the microscopic examination, if it be possible, to an expert pathologist. The pathologist, however, can only give an opinion on the fragment submitted to him, and not on the disease itself from which the patient suffers, except when he finds in this fragment *positive* characteristics of malignant new growth. Examination must not be limited to the investigation of one single section, but must be extended over the whole fragment, which accordingly has to be cut up into sections, unless already previously the diagnosis of malignancy can be established with certainty. If necessary cautious intralaryngeal removal and microscopic investigation of fragments of suspected growth must be repeated several times, *unless meanwhile clinical symptoms which are incompatible with our present knowledge of the symptomatology of benign growths, establish with certainty the malignant character of the suspected growth.* In such cases radical operation, if otherwise indicated, is *not* to be postponed until the diagnosis has been confirmed by the microscope.

I feel sure, gentlemen, that if you will proceed upon the lines of this advice, which is derived from the collective experience of the most prominent laryngologists of the world, you will serve the interests of your patients infinitely better than if you reject the help of the microscope on the strength of theoretical dangers. As to the methods which Dr. Mackenzie proposes to substitute for the aid given by the microscope—viz., exploratory thyrotomy, I have not a word to say against it so long as its use is restricted to cases which really demand it,—i.e., to cases in which clinical experience leaves the nature of a suspicious growth doubtful, in which microscopic examination is either impossible or inconclusive, and in which the conditions of the individual case make it imperative to arrive without delay at a correct diagnosis. If, for instance, in circumstances such as those just described, the growth

were situated very near the posterior wall of the larynx and threatened to invade that part I would certainly propose exploratory thyrotomy, as by waiting longer the chances of effecting a cure by less serious radical operation might be lost and total extirpation of the larynx ultimately become unavoidable. But, speaking from large experience, I can truthfully say that it is only in a minority of cases that exploratory thyrotomy is indicated, and though the operation need no longer be regarded as a very serious one in itself still it is not altogether devoid of risk when the class of patients is considered who form the bulk of these cases—middle-aged or elderly men, often enough with all sorts of complications which render any operative interference anything but desirable. In addition, it must not be forgotten that no guarantee can be given that some impairment of voice might not result from thyrotomy. I should therefore not agree to its immediate routine use in all cases in which clinical experience leaves the nature of a suspected growth doubtful and be rather guided as to its employment by the circumstances of every individual case. With this I leave the diagnostic side of Dr. Mackenzie's proposals and come to his therapeutic suggestions.

3. The first of these is that early total extirpation of the entire organ with its tributary lymphatics and glands, whether the latter be apparently diseased or not, should be performed as the only possible safeguard against local recurrence or metastasis in practically all cases of malignant disease of the larynx as soon as the diagnosis had been established. It is true that in the last part of the paper it is admitted that there may be "exceptional" cases in which a "very small growth, distinctly circumscribed, remote from the middle line, and not of a specially malignant type may possibly be removed with safety" by extirpation of half of the larynx and the lymphatics on the corresponding side." But even this admission is made grudgingly, and from the whole tenor of the paper and the context of the paragraph in question it is perfectly obvious that operation for cancer of the larynx, to be in the author's opinion complete, ought to embrace nothing less than removal of the whole organ with its lymphatic vessels and glands. This recommendation is based upon the author's contention that the severity of surgical interference, when dealing with cancer, ought to be the same in whatever part of the body a malignant growth may be met with. This contention again shows a profound disregard of practical experience. Whilst no sane person has ever asserted that cancer is one thing in one part of the body and another thing in another, both careful clinical observation and the results of surgical interference have incontestably shown that—other circumstances being equal—both the severity of the required interference and recurrence after operation depend to a degree, the practical importance of which can hardly be over-estimated, upon the question of the primary localization of the malignant new growth. Every surgeon when called upon to give a prognosis and to operate in a case of epithelioma of the lip, the ear, or the penis knows that the prognosis with regard to recurrence is infinitely better, the amount of interference required much smaller than in a case of epithelioma of the tongue, or pharynx, or in a case of cancer of the breast. These facts are so fundamental and so generally admitted that I hardly think a single surgeon will be prepared to deny them.

Now the larynx with regard to this question occupies a very peculiar position, indeed. Exactly 25 years ago the late Professor Krishaber of Paris[25] proposed to divide malignant growths of the larynx into two categories, "intrinsic" and "extrinsic" forms. In the former are included tumors originating from the vocal cords, the ventricles of Morgagni, the ventricular bands, and the subglottic cavity within the borders of the larynx proper. The term "extrinsic" is applied to tumors originating from the epiglottis, the posterior surface of the cricoid plate, the arytæno-epiglottic folds, and the interarytænoid fold. This classification is much more than one of mere convenience. It signalizes a fact of the greatest possible clinical importance and one which has been confirmed by a quarter of a century's clinical observation—viz., that in the intrinsic variety the disease remains for a long time a purely local affection and shows only at a comparatively late period a tendency to metastasis, whilst in the extrinsic variety, owing to different conditions of lymphatic anastomosis, the neighboring glands are already affected at a very early period, and, indeed, are usually found to be invaded when the patient first comes under observation. There is nothing mysterious or inexplicable about this remarkable difference; it simply depends upon the fact that the lymphatics of the region, which constitutes the intrinsic variety, form much more a network of their own and anastomose much less freely with those of their neighborhood than those which supply the upper parts and external parts of the larynx. It is true that no complete agreement reigns as to the details of these conditions of the lymphatic supply amongst the various observers who have particularly studied this question, such as Luschka, Teichmann, Sappey, Poirier, Most, Cunéo, and de Santi.[26] Whilst they all are unanimous in declaring that the lower parts of the larynx, and the vocal cords in particular, are less richly supplied with lymphatics than the vestibular regions of that organ and that the lymphatics of each half of the larynx are relatively independent of one another, some of them are inclined to introduce subdivisions of a confusing character which are rightly rejected by de Santi in his recent paper, to which I would particularly draw your attention.

In all circumstances, however, the broad clinical fact is certain—that cancer occurring in the intrinsic region remains much longer a purely local disease, and is therefore amenable to less severe radical treatment than the same form of malignant disease when originating in the extrinsic region. Incidentally, I may here perhaps be allowed to remind you that this local difference arising out of the different conditions of lymphatic supply and anastomosis in the different parts of the larynx is not limited to what we observe in malignant disease. Exactly the same conditions obtain in diphtheria. Whilst early considerable implication of the cervical lymphatics forms one of the most conspicuous phenomena of diphtheritic infection when localized in the pharynx and the extrinsic region of the larynx almost the whole intrinsic regon might be lined with false membrane without any enlargement of the cervical lym-

phatics being present at all. The older generation will remember that this very fact was made one of the main arguments against the identity of diphtheria and croup.

I am extremely gratified that with regard to the all-important question just discussed I find myself in complete agreement with the leading authority concerning total extirpation of the larynx, Professor Gluck, who in his latest contribution to the question expresses himself verbatim as follows:[27] "If the anatomical character of the tumor, be it medullary carcinoma or scirrhus, is not without importance for the extent of the operation, the topographical relations according to the anatomical seat of the new growth are especially decisive. In particular, if we consider the region of the neck, every surgeon will nowadays admit that we can obtain in cases of circumscribed cancers—for instance, of the vocal cords—which have been diagnosed in time lasting results by conservative excisions, performed in a healthy neighborhood. In the case of the pharynx and pharyngeal part of the œsophagus, the conditions are quite different, owing to the lymphatic supply, and here we should place ourselves *cum grano salis* as a matter of principle on the radical point of view discussed when speaking of cancer of the uterus—i.e., even if the tumor be relatively small extensive operation must be performed if recurrence is to be excluded with any amount of certainty." It is the disregard of these practical facts which has led Dr. Mackenzie to his wholesale demand for total laryngectomy in all cases of laryngeal cancer.

Now let us consider this demand. I am glad, my views on this particular point having on more than one occasion been misunderstood, that I have the opportunity of stating plainly what I think of that operation after having seen a good deal of its immediate and more remote results. Nobody can recognize with greater admiration than I do, gentlemen, what enormous progress has been made in the technique of total laryngectomy since its first inception by Patrick Heron Watson in 1866. The work of Professor Gluck, of Berlin, in particular must be ranked with the greatest surgical triumphs of our days. When one has seen, as I have, cases of his in which the whole of the larynx with the neighboring lymphatic glands, part or the whole of the tongue, a large part of the œsophagus, several of the most important nerves and vessels of the neck have been removed for malignant disease, the patient surviving an amount of interference which seems well-nigh incredible, one can but bow before such achievements, and one must feel deeply grateful that surgical art should have made it possible to prolong life to those victims of the cruel disease who wished to live at any price or who are compelled to do so from higher motives. But, gentlemen, when this ungrudging homage has been given to the merely surgical aspect and when we now come to consider the extremely grave question of the further existence of these patients, a deep gulf opens between some of my surgical friends and myself. Professor Gluck, whose surgical achievements are equalled by his warm-heartedness, summarizes his views in his recent great paper[28] by saying that "if we can do things in surgery to-day which appeared impossible yesterday, we must in the first place consider it the paramount duty of medicine to prolong life," and some followers of his, M. Le Bec and M. Real,[29] note with approbation the following statement made by the same authority last year at Swansea:[30] "First of all, we must seek to prolong the life of our patient. Do not worry too much about his post-operative condition. Restoration of the function is a secondary consideration: the important point is, first of all, to do away with the imminent disease: this is my surgical faith."

Well, gentlemen, whilst willingly recognizing that this is a question in which opinions might legitimately differ, I confess that I cannot unreservedly go the length of Professor Gluck's conviction. It is no doubt our duty to prolong life, but when he says that we ought not to worry too much about the patient's post-operative condition and that restoration of function is a secondary consideration, I firmly maintain that at the time when the question of operation arises the further question ought to be taken into most serious consideration, whether the life thus prolonged is worth living. It is one thing to perform a brilliant operation, and thereby to prolong a patient's life; it is another to see him a few months afterwards dragging on a most pitiful existence. I do not speak here of the dangers of recurrence, particularly when these tremendous operations are undertaken in advanced cases. Proverbially "beggars are no choosers," and when a man has before him the prospect of certain death within a few months under great sufferings, and, on the other hand, a chance, although remote, of remaining free by submitting to a serious operation I should, *if the post-operative existence could be rendered worth living,* not only consider it legitimate for such an operation to be undertaken, but should strongly advise it. Even if, in such circumstances, a small percentage only of all those afflicted could be saved, this would be a gain, and if I were the patient myself I should certainly take my chance. But matters, in my humble opinion, are widely different if, in addition to the danger of recurrence, there is that—to my mind extremely sad—after-existence which has to be endured after successful removal. There are certain operations which mutilate not merely the body, but, as I expressed it on a previous occasion,[31] "take away a part of human existence." I know of none coming more under that head than total extirpation of the larynx. I shall not indulge in harassing descriptions and lay myself open to the accusation of sensationalism, but, soberly speaking, one must have seen a number of these patients some time after the operation with their difficulty of making themselves understood by other persons, with their difficulty in not a few cases in swallowing, with their total inability of following an ordinary occupation, and one must have witnessed the instinctive horror with which they are looked upon by other people, whereby in addition to their physical disabilities, grave mental distress is caused to the more sensitive amongst these poor patients, to realize what kind of existence it is that has been gained by this prolongation of life.

I may be told that this picture is too gloomy, that the after-existence is not invariably so sad as just described, that some patients were quite content with their lot. I do not doubt this. All I can say is that I have faithfully described the impression, which I have received from my personal experience, that this impression is deepening with every fresh case I see,

and that I firmly believe that my description applies to the great majority of all cases thus operated upon. Yet, gentlemen, with all this I do not wish it to be understood that I am an opponent of total laryngectomy. Far from it. Quite apart from the fact that I should consider it absolutely unpardonable to force my own opinions upon my patients because they happen to differ in their views of the value of life from my own, there are circumstances in which I should be most anxious to assist them in prolonging their life, however sad the after-existence may be. I have the profoundest admiration for the heroism of a man who, fully conscious what will be his lot in the event of a successful termination of the operation, yet wishes to prolong his life for the benefit of those dear to him. Thus a patient might desire to submit to operation because his family would get a pension if he could survive but one year more; thus another might do likewise because he wished to finish a scientific work, or to perfect an invention, the proceeds of which would benefit his family; thus a third, who had insured his life for a certain number of years, might desire to be operated on because in the event of his surviving for another year or two a material increase of fortune would be secured to his family. All these sentiments are simply admirable and considerations as to the kind of post-operative existence undoubtedly must be subordinated to them.

From the foregoing observations I trust you will have seen that I am certainly not an extremist, and I may further tell you that, acting upon my views, I have, in the course of the last year alone, myself sent three patients suffering from advanced malignant disease of the larynx, and in whose cases operative interference had been refused by British surgeons, to Professor Gluck. Even the fact that unfortunately two of them have within a few months after operation developed recurrence would not deter me from consenting to, or even advising in, future operation in similar circumstances. But one thing, gentlemen, I think is absolutely certain—i.e., that such grave operations ought only to be undertaken under two conditions: (1) that the diagnosis was absolutely certain; and (2) in the event of there being no possibility of saving the patient by a less mutilating operation.

With regard to the first of these conditions, it is one of the most surprising omissions in Dr. Mackenzie's paper that he should not have referred by one single word to the terrible situation which would be created for both the patient and the surgeon in the event of so serious an operation as that proposed by him being undertaken on the strength of a mistaken diagnosis.

I trust I am not an over-sentimental person, but if I had in any of the cases mentioned by me before in which I have myself committed errors in diagnosis advised total removal of the larynx I should be harassed by the recollection of that case to the end of my days.

But supposing that the diagnosis of cancer had been positively arrived at, is there really no possibility of saving the patient otherwise than by total extirpation of the larynx with its tributary lymphatics? I hold that to be disastrous teaching. Every case ought to be judged on its own merits, and, above all, Krishaber's classification must be taken into consideration. If a malignant tumor is situated on the posterior wall of the larynx; if the glands on both sides of the neck are already enlarged when the case comes under observation; if, although the disease may have begun as intrinsic carcinoma, it has already passed the borders of the intrinsic region, has involved both sides of the larynx, and has infected the cervical lymphatic glands on both sides, no doubt the only chance of possibly saving the patient lies in total removal of the organ with extirpation of the affected and the neighboring glands. But if the growth when first detected is confined to the intrinsic region, is limited in circumference, and has neither infiltrated the framework of the larynx nor infected the neighboring lymphatics, practical experience has taught us that it is indeed possible in a large number of cases to save the patient without resorting to the extreme measure of total extirpation of the organ with its tributary lymphatics.

Four methods here come into consideration: intralaryngeal removal, subhyoid pharyngotomy, thyrotomy, and hemi-laryngectomy. With regard to the intralaryngeal method, I have unfortunately had to differ on so many points from Dr. Mackenzie that it gives me genuine pleasure to say that at any rate I am at one with him when he says that "operation for laryngeal cancer through the mouth done almost universally to-day, it seems to me should no longer come within the range of serious consideration." I have on more than one occasion, and only last year again at Swansea, expressed myself in a similar sense, and therefore need to-day but briefly summarize the reasons of my objection. I reject intralaryngeal operations in cases of laryngeal cancer—which, by the way, I believe to be not nearly so universally practised as Dr. Mackenzie assumes—not because I deny the possibility of curing a few patients by this method, but because, in my opinion, the game is not worth the candle. I hold that it is a false ambition to claim cases of cancer of the larynx, even if in an early stage, even if circumscribed, even if situated on a vocal cord, as proper objects for intralaryngeal operation, because this method, whilst excellently adapted for the removal of growths from the surface, gives no guarantee whatever for the complete eradication of neoplasms infiltrating the mother soil and of removing a sufficient area of healthy tissue all round the new growth. The adoption of any method which does not permit the surgeon to remove with certainty not only the malignant growth itself, but also a sufficiently large healthy zone round it, is unsurgical, and is a contravention of the general rules of surgery in cancer. A further important consideration is that malignant disease of the larynx when once the organ has been opened is in the great majority of cases found to be considerably more extensive than had appeared to be the case from laryngoscopic examination, and finally, even after an apparently successful intralaryngeal removal of a malignant laryngeal growth, it will be imperative to keep the patient for a very long time under periodical supervision at short intervals in order to detect and, if so, at once to treat apparent recurrence, which, however, in most cases of that kind ought to be more properly called incomplete eradication. Taking all these circumstances into consideration I say with Dr. Mackenzie

that operations for laryngeal cancer through the mouth should no longer come into the range of serious consideration.

The second contingency—subhyoid pharyngotomy—can be dismissed in very few words. In malignant disease of the larynx it is only applicable in cases in which the disease is confined to the epiglottis, or to the arytæno-epiglottic folds and in which the neighboring lymphatics have not yet been infected. Apart from the fact that these contingencies are extremely rare, the operation in such cases had hitherto been attended, so far as public records go, by singularly large fatality, and although I have lately heard privately that better results have been obtained more recently, I am waiting for confirmation of these tidings before I see my way to recommend adoption of this method in cancer of the larynx.

4. But how about thyrotomy? Here we come to the last and, perhaps, the most extraordinary of Dr. Mackenzie's assertions. As already stated, he unreservedly condemns this operation in the following terms: "Thyrotomy with curettement or removal of all apparent (visible) parts diseased is not up-to-date surgery, is in direct defiance of the rules that should govern us in the treatment of cancer, and is a reversion to, and a resurrection of, a method of procedure that was discredited and abandoned half a century ago." I do not think that my characterizing this assertion as "extraordinary" is a bit too harsh when it is contrasted with another enunciation of Dr. Mackenzie's pronounced in 1895. In that year, on the occasion of a discussion on cancer of the larynx at the meeting of the British Medical Association in London, Dr. Mackenzie stated verbatim:[32] "I do not wish for one moment to depreciate the value of the removal of laryngeal cancer by thyrotomy. To do so would be to fly in the face of all experience." I do not know what has happened between 1895 and 1900 that has induced Dr. Mackenzie to do in 1900 the very thing which he deprecated in 1895—viz., to fly in the face of all experience. One thing, however, appears to me quite certain, and that is, that if an author not merely completely disregards the practical experiences of trustworthy members of his own profession and sweepingly condemns their procedures, but additionally flatly contradicts himself, he is bound to give reasons for his sudden change of front, instead of mere assertions, expressed in a manner which he must have foreseen could not but hurt the feelings of those who had obtained the most satisfactory results by the method which he so unconditionally condemns. But, incredible as it may seem, no reasons whatever are adduced in his paper for the attitude assumed and the suggestions which he made in the discussion of 1902—viz., that "in considering apparent cures from this, as well as other incomplete and therefore hazardous and unsurgical operations, two mighty possibilities should be for ever borne in mind: mistakes in diagnosis and the simple accident of good fortune"—are again not in the nature of proofs but of further assertions and can but add fuel to the flame. I know that Dr. Mackenzie is absolutely incapable of deliberately making a misleading statement, but in speaking of thyrotomy as being not up-to-date surgery, as being in direct defiance of the rules that should govern us in the treatment of cancer, and being a reversion to, and a resurrection of, a method of procedure that was discredited and abandoned over half a century ago, he none the less creates as wrong an impression in the mind of the uninitiated reader as if he had intended to produce it.

In the introduction to this paper I have reminded you that thyrotomy for laryngeal cancer was in 1878 discredited and subsequently practically abandoned because in these days advanced and therefore *á priori* unsuitable cases were subjected to an operation the technique of which at that time was anything but methodically developed. If twenty years afterwards, with improved technique, that operation has again been resorted to in a class of cases totally different from those in which it has been unsuccessfully employed at a previous period, it surely is not fair to describe a progressive and beneficial development of that character as "a reversion to, and resurrection of, a method of procedure that was discredited and abandoned half a century ago." And when Dr. Mackenzie speaks of thyrotomy as an "incomplete and therefore hazardous and unsurgical" operation, I must say that this description is very unjust. The advocates of thyrotomy take their stand on the basis of the same celebrated dictum of Virchow's, which Professor Gluck[33] has quoted as his guiding star: "If cancer be at its commencement, and often for a long time a purely local disease, it must be possible to cure it during that period by local treatment." Clinical experience has conclusively proved that intrinsic cancer of the larynx is prominent amongst those forms of malignant disease in which the disease not merely commences as a purely local affection, but remains, as a rule, for a comparatively long time limited to its original focus. If during that period its true nature be recognized, and an operation be performed, which not merely removes the tumor itself, but a sufficient area of healthy tissue in all directions round it, the patient has a reasonable chance of being lastingly cured. Such an operation is modern thyrotomy as first suggested by Mr. Butlin. Fifteen years' experience has shown that by its employment the disease can be completely and lastingly eradicated, and to describe it as an "incomplete and therefore hazardous and unsurgical" operation is wide of the mark.

The "two mighty possibilities" which Dr. Mackenzie invokes for the explanation of what he calls "apparent" cures—viz., "mistakes in diagnosis and the simple accident of good fortune"—can only raise a smile. Surely Dr. Mackenzie himself cannot seriously believe that not only Butlin and myself, but the whole British school of laryngologists, and additionally Chiari, Schmiegelow, and Moure, should for 15 years have been persistently favored by the "simple accident of good fortune"? As to the "mistakes in diagnosis," which are advanced as another "mighty possibility," I am unwilling to believe that Dr. Mackenzie could entertain such a low opinion of European pathological experts as to imagine that they should not be capable of diagnosing an ordinary epithelioma—by far the most common form of laryngeal cancer—when the entire growth has been submitted to them after radical operation. But whatever the meaning of his various explanations may be, I think I may assure you that no such wholesale mistakes as those alleged by him have

been committed, and as a proof thereof I beg to submit to you the microscopic preparations of 18 cases of my own, in 15 of which I performed thyrotomy, and in one hemi-laryngectomy, whilst in the two remaining cases the operations were successfully performed by my friend and former assistant, Mr. Ewen C. Stabb.[34] I should have liked to make the series quite complete and to submit to your inspection specimens of *all* the cases operated upon by me, but it really could not be foreseen, after I had for years made it a methodical practice to demonstrate my cases whenever possible, and often enough years after the operation, before the Laryngological Society of London, together with the microscopic preparations belonging to them, that it could be suggested that "apparent" cures by means of thyrotomy might be due to either good luck or mistaken diagnosis. Thus not in every case of mine have microscopic preparations been preserved. The number of slides, however, shown to-day is, I trust, representative enough to convince anybody who does not deliberately shut his eyes to plain facts that my operations have not been performed on the basis of a mistaken diagnosis.

And now as to the results of the operation so much deprecated by Dr. Mackenzie. Last year at Swansea I reported from my own practice 20 thyrotomies,[35] with or without removal of small fragments of cartilage in cases of undoubtedly malignant disease of the larynx, with 19 recoveries, two quite doubtful recurrences, and one death.[36] In two of the cases then reported the operation had been too recently performed to allow one to speak of lasting cures. In one of these cases the patient has remained perfectly well, in the other it was found that the operation had not been extensive enough[37] and a second thyrotomy was performed within two months from the first. After the second operation the patient has remained well. As in both these cases more than a year has now elapsed since the performance of the operation, there being not a trace of recurrence, and as I am firmly convinced from personal experience that no recurrence need be feared if the patient has remained well for a full year after operation, I am now—irrespective of the incomplete operation which had to be repeated—in possession of a material of 20 thyrotomies performed for undoubted malignant disease of the larynx, between 1891 and 1904, with one death, two doubtful recurrences, and 17 lasting cures, bringing the percentage of successful cases in my own practice within that period up to 85 per cent.

I state these results with a feeling not of vain-gloriousness but of deep and sincere thankfulness that I have been privileged to preserve a number of valuable lives by an operation the character of which is little dangerous, and the results of which allow the patient not merely to live on but to lead a life in all respects worth living. In this connection it deserves particularly to be mentioned that the great majority of cases have regained a surprisingly good, although, of course, more or less husky voice, and that in a few cases only have their vocal powers been reduced to a whisper. Out of the seventeen patients who permanently recovered from the operation three died several years afterwards from affections altogether unconnected with the original disease: one, six years after operation from an acute abdominal affection; the second, three and a quarter years afterwards from embolism of the heart or lungs; and the third, four years afterwards from pneumonia. The remaining fourteen are all alive and well, as I have ascertained only recently by renewed inquiry. My oldest successful thyrotomy now dates back to June 2, 1891—i.e., more than thirteen years ago, and I have other patients living, and in good health, in whom the operation was performed twelve, ten and nine years ago. In addition to the 20 cases just named, I have performed three further thyrotomies in the course of the present year. All three patients have made an excellent recovery. In one of them, however, in which the patient had, in spite of my urgent advice, unduly postponed the operation, recurrence has unfortunately taken place and I have had to perform partial laryngectomy on the eve of my departure for America. The other two cases are of too recent date to be included as yet in the class of permanently cured cases.

It appears to me that no better reply could be given to Dr. Mackenzie's contention than the plain and well-authenticated facts which I have just stated to you. I have nothing to add to my former descriptions[38] concerning the technique of the operation, except that in my last four operations I have used with great advantage the excellent shears, which I am showing here, invented and recently described by my friend, Mr. Ernest B. Waggett,[39] for the purpose of cutting through the ossified thyroid cartilage.

From the foregoing facts it will not surprise you if I most warmly recommend the performance of thyrotomy in suitable cases of intrinsic laryngeal cancer. But in doing so permit me, gentlemen, to submit to you two serious words of warning. Already once before I said[40]: "Thyrotomy with simple removal of soft parts has been discredited by being expected to do impossibilities. I would not like this fate to be repeated through my fault." I stated this with special reference to the necessity of extending thyrotomy into hemi-laryngectomy if in the course of the operation it should be found that the disease was more advanced than had been concluded from mere laryngoscopic examination. Nevertheless, I am afraid that this warning has not been universally taken to heart. Last year at Swansea I referred to eight cases of thyrotomy reported on the occasion of the Madrid International Medical Congress by Dr. Botella from Professor Cisneros' clinic. In no less than six of these cases recurrence had taken place from within one month to two years after operation. Whilst being unable in the absence of details of the cases to give a satisfactory explanation of this astounding record of failures, I suggested that there must have been something wrong with either the selection of the cases for thyrotomy or with the technique of the operation itself. Since then Professor Cisneros has published a paper[41] on Thyrotomy in Laryngeal Cancer in which he states (page 315) that he treats pedunculated tumors which are situated on the border of a vocal cord and which do not impede or at any rate completely paralyze the movements of that cord by intralaryngeal treatment, whilst he performs thyrotomy in cases of tumors implanted on the whole or greater part of a vocal cord with *complete paralysis of the latter* (the italics are my own).

From this description it appears to me that Professor Cisneros treats those cases which I would treat by thyrotomy by means of the intralaryngeal method, and performs thyrotomy where I, in the majority of cases, would probably perform hemi-laryngectomy. For when a vocal cord is completely fixed—this, I think, is what he means by speaking of "complete paralysis"—the presumption seems justified that the infiltration had already extended very deeply. Want of success of simple thyrotomy when performed under such circumstances is not surprising. Permit me, therefore, earnestly to repeat my advice that thyrotomy should be performed only when the new growth is still limited to the intrinsic region of the larynx, is still circumscribed, is not too extensive, and does not infiltrate too deeply, and that in such circumstances a sufficient zone of healthy tissue should be included in the area to be removed *everywhere* in sufficient distance from the new growth. Should it be found in the course of operation in a case which seemed on laryngoscopic examination to fall under this category, that the disease is more extensive than had been presumed from laryngoscopic appearances, the operator must not hesitate to extend his operation into hemi-laryngectomy, or if both sides of the larynx should be involved into total extirpation. It is only by the observance of this cardinal rule that thyrotomy will gain the place which is due to it amongst radical operations for cancer of the larynx.

The second request I have to make is this: whilst thyrotomy is still on its trial everywhere except in Great Britain let me ask you to proceed strictly on the lines suggested by Mr. Butlin and myself. I do not believe in the finality of our present technique, and I willingly admit that it may be possible, when once thyrotomy has everywhere gained its place amongst recognized operations for laryngeal cancer, to improve upon the method of operation by means of which we have obtained such satisfactory results. But whilst the operation is still on its trial do not complicate matters by prematurely introducing modifications! I am more particularly induced to make this observation because during a very recent discussion of this question[42] it has been suggested to altogether omit tracheotomy and the introduction of a tampon cannula in the course of the operation. I am not at all inclined to dispute that at some future period this suggestion may be successfully carried out. As matters stand, however, at present it ought to be remembered that every failure will, without consideration of its special cause, be laid at the door of the method itself, whilst thyrotomy is fighting for its very existence. If, on the other hand, you will proceed exactly on the lines suggested by Mr. Butlin and myself, with regard to both diagnosis and technique, I firmly hope that in the near future we shall hear of similarly good results being obtained in America as it has been the privilege of British laryngologists to report during the last 15 years. I may perhaps be permitted here, speaking before an American audience, strongly to repeat a former recommendation of mine[43]—i.e., that only chloroform, not ether, should be employed in these operations. Their one real danger consists in complications on the part of the respiratory organs and every irritation of these parts should therefore be strictly avoided. That it is the tendency of ether to produce such irritation is known to everybody. I am induced to make this observation because I have learnt from Dr. J. Solis Cohen that ether narcosis is almost exclusively used in the United States in these operations.

The only remaining operation to be discussed is hemi-laryngectomy, or partial extirpation of the larynx. Already last year at Swansea I expressed my conviction that partial extirpation of the larynx will come to be more rarely performed in proportion to the diagnosis of malignant disease being arrived at more and more early, when thyrotomy will suffice. It should, in fact, only be employed when the disease is found to be too advanced and too deeply infiltrating to be eradicated by thyrotomy with removal of soft parts only. That, in such circumstances, its results are not likely to be so satisfactory as those of thyrotomy in early stages is obvious; the disease having been so much longer in existence there is reason to fear that it may no longer be purely local and that metastasis may already have occurred. My own experience, limited as it is, bears out that consideration. I have only performed four hemi-laryngectomies. In one case, the patient, as previously reported, died 24 hours after the operation from ether poisoning, the anæsthetic having been administered per rectum. In the second case, a year and a half after the operation, the cervical lymphatic glands above the clavicle, *not* those in the immediate neighborhood of the larynx, were found to be enlarged and there was evidence of infection of the mediastinal glands. The patient is still alive, but going down hill, and the fatal end, I am afraid, will not long be delayed. In the third case the patient remained free for fully four years after the operation, but then began to expectorate blood and died with unmistakable symptoms of cancer of the liver, whilst there was at the same time dulness at the base of the right lung. In that case the cervical lymphatic glands remained perfectly free throughout. The fourth case is, as previously stated, of quite recent date. In view of the possibility of a development, such as occurred in my second case, I should not offer any objection to extirpation of the corresponding lymphatic glands even if apparently unaffected in cases of hemi-laryngectomy for cancer, although, as my third case shows, even that measure, when once metastasis has actually occurred, does not give the patient a guarantee against recurrence. That such extirpation should, as a matter of duty, be performed in cases of hemi-laryngectomy if the glands are in the least shotty or visibly enlarged goes without saying, but in such cases the prognosis anyhow is unfortunately very doubtful.

And now, gentlemen, I am at the end of my task. I have, as promised, nailed my colors to the mast of practical experience as against theoretical possibilities. At the same time I trust I have succeeded in showing you that the principles upon which my views are based are not purely empirical, and are in all points in concord equally with the experiences of practice and with the achievements of science. Let me summarize, then, what I have endeavored to establish under the form of the following theses, which may serve as a basis for the discussion which I understand is to follow the reading of this address.

1. It is of the greatest importance that the diagnosis of laryngeal cancer be made at the earliest possible moment. For this purpose it is most essential that the still prevailing notion—viz., that malignant disease of the larynx is from the first attended by all sorts of grave constitutional symptoms—be completely eradicated and that the attention of the general practitioner should again and again be drawn to the fact that there are no more promising cases for radical operation than those in which the disease is at first manifested by nothing else than by obstinate hoarseness, occurring, without any apparent cause, in middle-aged and elderly persons.

2. Clinical diagnosis arrived at from the history and subjective symptoms of the case, from laryngoscopic examination, from accessory circumstances of importance, such as the patient's age, etc., has reached a certain degree of perfection, and enables us in a good many cases to make a correct diagnosis at an early stage of the disease; it is, however, by no means absolutely perfect, and occasional mistakes occur even in the practice of those most experienced.

3. In these circumstances clinical diagnosis ought, whenever possible, to be confirmed before radical operation of any kind is undertaken, by the intralaryngeal removal and microscopic examination of a fragment or fragments of the new growth. This, however, should only be done if the patient previously consents to immediate radical operation being undertaken in the event of the microscope confirming the clinical diagnosis. Should this be the case the practitioner's position will have been materially strengthened. The microscope, however, is by no means infallible in these cases. Should its evidence be negative or inconclusive, the intralaryngeal removal and microscopic examination of fragments should either be repeated, if necessary, several times, or, if the clinical symptoms do not warrant postponement, exploratory thyrotomy should be undertaken.

4. The intralaryngeal method is from its very nature unsuitable for the radical removal of malignant new growths of the larynx.

5. Subhyoid pharyngotomy, apart from being applicable in a very small number of cases only of malignant disease of the larynx, is still *sub judice* with regard to its advisability in such cases.

6. Thyrotomy, if undertaken in suitable cases, and at a sufficiently early period, and if performed on the modern lines which experience has shown to be successful, is a perfectly ideal operation in intrinsic cancer of the larynx.

7. Hemi-laryngectomy comes into question only when it is found after opening the larynx that mere thyrotomy will not suffice. When performed it may be accompanied by removal of the tributary lymphatics, even if apparently not diseased.

8. Total laryngectomy should be exclusively reserved for extrinsic, and for those cases of intrinsic, cancer, in which both sides of the organ are affected, and in which the disease has proceeded too far to be eradicated by milder measures. When performed it should be accompanied by the removal of the laryngeal lymphatics on both sides of the neck.

It the adoption of these principles should meet with your approval, gentlemen, there will be an end to the deplorable schism which has of late separated the surgeons and laryngologists of various countries with respect to the diagnosis and treatment of malignant disease of the larynx, and we may justly hope that in striving shoulder to shoulder we shall advance science and benefit our patients.

THYROIDECTOMY FOR EXOPHTHALMIC GOITRE. BASED UPON FORTY OPERATIVE CASES.

By CHARLES H. MAYO, A.M., M.D.,
ROCHESTER, MINNESOTA.
SURGEON TO ST. MARY'S HOSPITAL.

The subject of goitre is still an unsettled question, at least in many of its phases, although there have been written over fourteen hundred articles and books upon the subject. While it is quite probable that nothing new may be presented, still discussion develops suggestions which may prove of benefit at this time, as our more advanced knowledge of the lymphatic system and the glands both with and without ducts, renders the subject of internal secretions of exceeding interest.

We will not enter into a description of the anatomy, pathology, or symptoms of Graves' disease, but, to avoid much repetition, will assume at once, for the sake of brevity, that those interested understand what is meant by the disease in question.

These patients present themselves to the physician for the relief of symptoms which he attributes to exophthalmic goitre, or they come to have a confirmation of diagnosis, and relief, if possible. While there are many symptoms of Graves' disease, more or less of which may be present, the one symptom common to all is tachycardia without other known cause, and with this is usually associated the goitre and the prominent eye which is so characteristic. These two symptoms, from their late or non-appearance, have often delayed the early diagnosis of the disease. A not uncommon type is one in which the symptoms of Graves' disease are suddenly grafted upon a patient who has had colloid cystic goitre for some years. It is also true that patients without, as well as with goitre, seem at times to develop very many of the symptoms of exophthalmic goitre, and yet recover very soon, often without any special treatment.

We must assume that there may be a combination of causes for exophthalmic goitre, accepting the gastrointestinal toxæmia of certain medical writers as a part with the thyroid element the major, and the nerve theories as not the least in the combination of circumstances. To read the medical side of this question it would seem that the internist and surgeon are gradually drifting apart. The internist attempts to convict the surgeon with his own reports of multiplicity of operation, large mortality, and the not infrequent failures, and lauds the medical, hygienic, and diathetic treatment. Judging from personal knowledge, it is probable that most of these cases which finally see the surgeon, have already run the gauntlet of all known remedies for the disease, and usually at the hands of several practitioners. We think that it would be rare indeed for a surgeon who was capable of making one of the operations for its relief, to recommend operation at the inception of an attack of Graves' disease, unless it were possibly a case grafted upon an already goitrous patient.

Practically, all surgeons have passed years in general practice, and have seen the ordinary exophthalmic patients improve under medical treatment, electrical treatment, no treatment, and the mental suggestion of Christian Science. We all know that some cases resist all efforts at relief; what shall be done for them?

From the experiments in blood pressure, shock and resuscitation carried out by Dr. Crile, it would seem that blood pressure is maintained by the vasomotor system as a direct nerve type and by the internal secretions as a blood type, acting upon the vessels even when the head is removed. From what little knowledge of the internal secretions we now possess, this equilibrium of the blood pressure must be in great part sustained by the opposing action of the secretion of thyroid and suprarenal glands. One of the functions of the suprarenal gland secretion serves to greatly increase blood pressure, and through its action upon the capillaries, it greatly reduces all peripheral circulation. While a tension is occasionally noticed in the pulse of Graves' disease, it is more often low, especially when the disease is active.

Were it possible that these secretions in effect served to maintain an equilibrium of certain blood elements, it would readily explain the effects of an excess of thyroid in one case, and an excess of suprarenal in another. Thus the loss or absence of thyroid tissue in the young is followed by cretinism from the unobstructed action of the suprarenal glands, contracting all peripheral capillaries and preventing growth and development. In adult life, the same conditions cause intellectual degeneration, and myxedema. While it is contended that the thyroid secretion does not, when given to the system, cause Graves' disease, it is certain that some of the prominent symptoms may be thus produced. We must admit also, that the thyroid employed is changed and given in an abnormal manner, as compared with the constant delivery of the internal secretions by means of the lymphatic system acting in great part as ducts. The hard and practically dry gland of this disease, as compared with the juicy colloid cystic variety, would indicate unusual activity as well as delivery of the contents of the acini, while in the colloid goitre the secretion may be retained, at least in part, and even in cases without goitre, a careful examination usually discloses a small unilateral or bilateral tumor, which lies deeper, but is firmer than normal.

What has been done surgically? First, exothyropexy, or the permanent exposure by incision, of the thyroid lobes lifted external to the skin. This operation is now rarely performed. Second, ligation of the thyroid arteries. Third, operations upon the cervical sympathetic ganglia, after the suggestion of Edwards, and developed by the work of Jaboulay and Jonesco, for the relief of several diseases. Fourth, thyroidectomy, which we will discuss later. Fifth, the apparent phychological effect of operations upon distant parts of the body we will not consider.

It has been our fortune, or misfortune from its difficulties, to operate upon several cases of cervical adentitis which had been exposed for many times to the *x*-ray. It was noted that the lymph system was greatly sclerosed. As this was in line with the reported action of the *x*-rays upon glandular activity, we applied this treatment to ten cases of very marked exophthalmic goitre during the past year, to first reduce glandular activity, and second, reduce absorption by its possible effect upon the lymphatics. While I would not as yet say that any of these cases are cured, they have certainly been markedly benefited; first, in the general nervousness; second, in tremor of the muscles; third, in tachycardia; and last, in the exophthalmus. The benefit is sufficient to soon give this method a place in the treatment of

Graves' disease, or at least make it a preparatory treatment to a prospective surgical method at a later period.

The symptoms were well developed in all; all improved. The three cases presenting the most marked symptoms had been under observation from one to two years at the beginning of *x*-ray treatment, having materially improved, but reached a stationary condition under medical treatment and rest. All three had marked exophthalmus, choreiform, jerking, and pulse from 120 to 140. In the three cases, choreiform movements disappeared; exophthalmus markedly diminished in one, improved in one, and almost disappeared in the third. Pulse—patient at rest—68 to 70 in one, 75 to 85 in another, and 90 to 98 in the third. Circumference of the neck, taken around the most prominent part of the goitre—diminished from ½ to 1¼ inches. One lost 15 lbs., one gained 10 lbs., and one gained 49 lbs. Two cases of well-developed symptoms, but no exophthalmus, so far recovered that a diagnosis would be impossible at the present time. We still have confidence in belladonna in improving the tachycardia and nervous symptoms, preparatory to operation in certain cases of doubtful operative risk.

Curtis' report of Kocher's operative cases in this line, gives twenty-nine cases of ligation of the thyroid vessels, with one death, and thirty-eight of partial thyroidectomy, with three deaths. Our experience is from one hundred and twenty-eight operations upon the thyroid gland, with eight deaths. Of these, one followed the removal of a cancerous thyroid from collapse of the trachea, one from pneumonia in colloid goitre, and the other six deaths were in the exophthalmic cases, of which there were forty. Two of these deaths were of patients who should not have been operated upon, as their condition was so aggravated as to almost class them as moribund previously to operation, one dying upon the table. All had received prolonged medical treatment. During the past year, two such cases were seen with regard to the advisability of operation, but with a knowledge born of bitter experience, both were refused. One died in a week, the other lived a few weeks, but both deaths were medical. In the last twenty-five cases operated for exophthalmic goitre, there were but two deaths. The shortest duration of the disease was five months, and the longest several years.

The anæsthetics have been cocaine, chloroform, and ether, preceded twenty minutes by one-sixth grain of morphine hypodermically. Ten cases were completed under cocaine infiltration, two cases required, in addition, chloroform, before completion. We choose cocaine for some of the worst types of nervous cases, especially with a rapidly fluctuating or irregular pulse; but can see no difference in the character or degree of shock or thyroidism in local or general anæsthesia. Cocaine is also used if one lacks confidence in the anæsthetist. Our preference is for ether. During the anæsthesia, should much mucus accumulate in the trachea and bronchi, the patient is allowed to come out of the anæsthetic sufficiently to clear the throat, and the chloroform is substituted. The Kocher collar incision is used, and a complete exposure of the gland made, cutting everything which impedes access to it. One-half of the gland, and possibly the isthmus, is taken.

According to Dr. Sifton, the anatomist of Milwaukee, the right recurrent laryngeal nerve closely approaches or is in contact with the right inferior thyroid artery, while on the left it is over one-fourth of an inch back, and an effort would be required to injure the nerve upon that side. The method of removal by extirpation is the rule, as in these cases there is usually very little capsule, and enucleation is out of the question. What can be left of the posterior capsule is a great protection, especially upon the right side, for the reasons stated above.

Thyroidism of some degree is common. It is not from rough handling of the unbroken tumor and forcing secretion into the veins. If so, it would be equivalent to hypodermic injection into a vein with immediate effect, when in reality it comes after some hours, and is due, apparently, to absorption of the wound serum, with some thyroid secretion in suspension. Thus many of the symptoms of Graves' disease are not uncommon for the first few days following the removal of ordinary colloid cystic goitre. For this reason, we drain exophthalmic goitre wounds as freely as we would a septic process. If there is anything which increases absorption, in wound or gland, it is loss of blood. Therefore, should the patient unavoidably lose a quantity of blood, every effort should be made early to replace the quantity lost, or more, by salt solution. This is true also of operations upon exophthalmic patients who are operated upon for other necessary surgical conditions. We have had one patient, afflicted with Graves' disease, die four days after the removal of a twisted pedicle ovarian cyst, with all the characteristics of a death following the removal of the goitre, excepting the delay for two days, of the severe symptoms. For the relief of the thyroidectomy and increased tachycardia, suprarenal extract has a marked effect, but seems to be somewhat difficult of permanent control. The benefit obtained from atropine and morphine is often very satisfactory.

We do not wish to be understood as objecting to operations upon the cervical sympathetic, as it is very certain that good results are thus obtained; still such operations have considerable mortality, and also the same disagreeable symptoms often following extirpation. We have, therefore, chosen to work directly upon the organ we have considered affected in operating for the relief of this condition. Could we eliminate more of the hopeless and yet operate upon medium and severe types of Graves' disease, the results of thyroidectomy would justify the operation and compare favorably with those obtained by other methods.

Our own cases show marked improvement of all who survived the operation. Of these, 50 per cent. made a very early recovery, especially of the severe symptoms—tachycardia, nervousness, and tremor; 25 per cent. did so after several months, and 25 per cent. were improved, yet suffer from irregular recurrence of some of the major symptoms.

The improvement noted was first a relief of the nervousness, the irregular twitching and jerking, not unlike chorea, next the tachycardia, and the tremor, while the exophthalmus, if at all marked, seemed last to disappear, although relieved in some extreme cases.

Our rules concerning the cases of Graves' disease which come to us for operation, are to operate, if their condition is fair, but, if the pulse is from 130 to 160, or if it suddenly fluctuates in tension and rapidity, if there is anæmia, with swelling of the feet, the patients are placed upon the belladonna treatment for some days. The more severe types are also given *x*-ray exposures in addition, which is continued from two to six weeks.

Of the six deaths, one occurred upon the table as the final skin sutures were being placed, two occurred at from fifteen to eighteen hours ofter operation, and three deaths occurred at from twenty-four to seventy-two hours. They suffered from an exaggeration of the previous symptoms: the jerking,

tremor, increasing rapidity of pulse and exophthalmus. The degeneration of the heart muscle will account for some of the sudden deaths, as pointed out by Prof. Fenger, while the absorption of thyroid, shock, anæmia, and general nerve exhaustion will account for most of the other deaths which were not due to the anæsthetic.

TWO CASES OF CHRONIC NEPHRITIS TREATED SURGICALLY.

By JAMES A. NYDEGGER, M.D.

U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

I WISH to report the results of decapsulation of the kidney in two cases of chronic Bright's disease which came under my observation last year.

CASE I.—C. W., age 54. Came under observation May 31, 1902. Family history negative. Previous history, had an attack of illness similar to the present one some eight years ago from which he thinks he recovered. Otherwise he has had good health up to about three weeks ago, from which time he dates the beginning of his present trouble. Is a moderate drinker. He is a large framed, well-nourished man. He has moderate dyspnœa, pallor is rather marked, there is some loss of strength, some ascites is present, and there is a moderate sclerosis of the radial and temporal arteries. The area of the heart dulness is increased downward and outward from 2 to 3 cm. The valve sounds are normal save for a booming sound at the apex. Is passing an increased amount of urine, averaging from 2,300 c.c. to 2,400 c.c. daily, of a specific gravity of 1.010, containing 27 grains of albumin per litre (Esbach), and a few granular casts and leucocytes. There is some œdema of the legs. He has some headache, and there is partial loss of appetite, and nausea following the taking of food. The diagnosis is made of chronic interstitial nephritis.

Under rest, diet and medication the œdema of the limbs disappeared and the ascites lessened, but there was no improvement in the general condition. The course of the disease was slowly downward. The patient had now been under observation for a period of nine and a half months. Decapsulation was advised in hopes of relief.

Operation was performed on March 18, 1903, under chloroform anæsthesia. The right kidney was selected. The oblique lumbar incision was used. A horizontal incision was made over the outer part of the twelfth rib and the outer two-thirds of it resected. The kidney was reached and drawn down into the incision, and the thick covering of fat divided and pushed to the sides. The kidney was found to be contracted to about one-half normal size. The capsule was closely adherent to the cortex, and was removed with considerable difficulty. A blunt-pointed dissecting forceps was found useful to catch up the projecting edges of the capsule which was detached in fragments. Numerous urinary cysts varying in size from a pea to a small hazelnut were present on and in the cortex. The kidney was replaced in its envelope of fat. The incision was closed save for a small opening through which an iodoform gauze wick was carried down to the posterior surface of the kidney for drainage. There was a large outflow of serum and urine lasting for several days.

Following the operation for some three weeks or so the case did well. Some collections of pus formed under the skin near the margins of the incision. These were opened and drained. The percentage of albumin in the urine increased decidedly. There was no diminution in the secretion of the urine until towards the first part of the fourth week, when it began to decrease rather rapidly. The headache, nausea and loss of appetite became more pronounced. Towards the end the albumin ranged from 95 to 100 grains per litre. Uræmic symptoms set in and resulted in death May 3, 1904.

At the autopsy the clinical findings were confirmed. The kidney from which the capsule had been removed appeared smaller than at the time of operation, and was closely covered with a white fatty scar tissue closely adherent to the cortical substance. The cortex was pale and thin and readily broke down under pressure. The urinary cysts were less numerous than at the time of the operation. The left kidney was also much reduced in size but not to so great a degree as the right one, and showed no cysts. The capsule was also less adherent.

CASE II.—W. C., colored, age, 51, came under observation December 16, 1902. Family history negative. He has had yellow fever and has had more or less rheumatism all the time for three years. Has had attacks of headache for the past three years. At first the attacks would come on about once every week, but later they became more frequent. He is not a drinker. He is a man of large stature and is well nourished. The abdomen is very fat, the lower eyelids are puffy, there is some enlargement of the heart downward and to the left, and the aortic second sound is somewhat accentuated. He is passing an increased amount of urine, specific gravity, 1.010, containing a large amount of albumin, some red corpuscles, a few leucocytes, and some epithelial cells. He is suffering with a severe occipital headache which is nearly always present, but becomes much worse at frequent intervals. The diagnosis was made of chronic parenchymatous nephritis.

Under treatment there was some abatement of the headache, but after a time drugs had no effect on it. The amount of urine was irregular. A marked decrease in amount was generally followed by the return of severe headache. On March 30, a note was made that his condition had grown steadily worse; he was then passing from 1,750 to 2,000 c.c. urine daily, containing three and three-fourths grains of albumin per litre (Esbach). Operation was advised.

The operation was performed on April 15, 1903, under chloroform anæsthesia. The right kidney was selected. An oblique lumbar incision was made with a horizontal one over the twelfth rib, with resection of the outer two-thirds of the rib. The patient was very fleshy, and the kidney was reached and brought down into the incision with some difficulty. The kidney was enlarged. The capsule was split and detached easily with the fingers. The incision was closed save a small opening for drainage through which an iodoform gauze wick was carried down to the kidney. The outflow of serum was small, and the drainage was removed in a few days and the opening healed by granulation. Following the operation there was almost complete relief from the severe headaches which continued so, save for a slight return at intervals.

April 25. Urine averages from 1.000 to 2.000 c.c. per day since operation and contains three and a half grains per litre of albumin.

May 13. The patient is feeling much improved. The urine contains two and a half grains of albumin per litre.

May 25. The headache has about disappeared. The urine shows five and a half grains of albumin per litre.

June 10. The patient declined operation on the other kidney. He has improved much since the operation and is slowly improving. Albumin is present, one-third grain per litre. This patient was last heard from (by letter)in August, 1903, and was following his vocation, that of a stevedore, and reported himself as feeling well.

It is interesting to note that in Case I. there was a decided increase of albumin in the urine following the operation, while in Case II. there was no increase of albumin, but rather a decrease. An interesting feature in Case II. was the almost instant relief from the headaches following the operation. This was most marked and continued so. This patient could not be considered recovered at the time discharged, as only one kidney had been decapsulated, but that he was greatly benefited could not be doubted. It is to be regretted that an unforeseen emergency prevented the double decapsulation in this case, as was originally contemplated.

I think the above cases represent fairly well the two classes of cases we have to consider in the surgical treatment of this disease. Class one, those which are benefited and finally cured. Class two, those which are not benefited by surgical intervention. Case II. of the above would fall in the first class, and Case I. in the second class. After the disease has advanced beyond certain limits, not yet well defined clinically, it would be harmful to operate. What is desired is to have this limit established. For this reason time must elapse to demonstrate the value of this operation. Surely it opens up a field in surgery which promises considerable good.

With regard to the way in which decapsulation benefits. The autopsy in Case I. showed the kidney operated on to be covered with a rather dense, smooth, white scar tissue, which seemed to offer a poor means of transmitting an increased blood supply to the cortical substance. Perhaps we should look more to the theory that the decapsulation relieves internal cellular pressure and thereby allows the compressed cells to return to their normal relations and functions.

PARALYSIS OF THE LEFT RECURRENT LARYNGEAL NERVE IN A CASE OF MITRAL STENOSIS.

By JOHN G. SHELDON, M.D.,
Telluride, Colorado.

Mrs. H., 38 years of age, came to me in March, 1902, for a diagnosis of a pelvic condition from which she had suffered for several years. At this time I found she had a well-defined, but compensating, mitral stenosis. Ten months later I was called to see the same patient, suffering from an attack of cardiac insufficiency. She complained of dyspnœa, cardiac palpitation, irritability of the stomach, and swelling of the lower extremities.

The patient was poorly nourished. The pulse was rapid and irregular, and a moderate degree of cyanosis was present. The cardiac impulse was easily seen. There was no systolic retraction of the chest walls. Percussion showed the area of relative cardiac dulness markedly increased, especially in the transverse diameter. The dulness extended one inch to the left of the left nipple line, and one and one-half inches to the right of the right border of the sternum. The apex was in the sixth intercostal space. A well-defined thrill could be felt. It was most intense in the fourth interspace to the left of the sternum, and terminated with a pronounced shock as the cardiac impulse occurred. Auscultation showed a presystolic and a systolic murmur; a "snappy" first sound and accentuation of the second pulmonic sound. The liver was diffusely enlarged and was tender. There was slight œdema of the lower extremities. The remainder of the examination revealed nothing of importance.

The patient was placed in bed and cathartics and digitalis were ordered. She soon recovered from the incompetency and resumed her occupation as a housewife. About six months later she took a rather long walk in the hills, and that evening experienced considerable difficulty in breathing. The next morning she was dyspnœic and could not speak above a hoarse whisper. She complained of little cough and had no pain in the region of the larynx. Examination showed a mitral stenosis, with a rapid and irregular pulse, and with enlargement and tenderness of the liver. The left vocal cord was in the cadaveric position and was immovable. The larynx showed no evidences of inflammation.

The patient was put to bed and digitalis was ordered. In 48 hours the symptoms of incompetency began to disappear, and there was a slight improvement in the voice. She improved rapidly, and at the end of one week felt very well and could speak in a normal tone. Laryngeal examination at this time showed that she had control of both vocal cords.

The presence of the mitral stenosis, the intermittent paralysis of the left recurrent laryngeal nerve, synchronous with the cardiac incompetency, and the absence of signs or symptoms of aneurysm, tumor, or adhesions, led me to make a diagnosis of temporary paralysis of the left recurrent laryngeal nerve, caused by the left auricle pressing the nerve against the aorta and pulmonary artery.

Cases of mitral stenosis with involvement of the left recurrent laryngeal nerve are occasionally reported, but they are of rare occurrence. Osler has seen two cases; Ortner and Alexander report cases, and Herrick reports one case of left recurrent laryngeal paralysis in a patient having mitral stenosis and concretio cordis. The reported cases are few, but they may not represent accurately the relative frequency of the condition. It is probable that some cases of intermittent paralysis, corresponding to the one reported by Alexander (*Berliner klinische Wochenschrift,* No. 6, Vol. XII.) and to the case herewith reported, have been overlooked or incorrectly diagnosed.

I am of the opinion that these cases can be diagnosed correctly in most instances. The presence of left recurrent laryngeal paralysis, as shown by the voice symptoms and by laryngoscopic examination, would indicate the necessity of a thoracic examination to reveal the cause. Russell has shown that the recurrent nerve has a double cortical supply. It is not known that unilateral or bilateral vocal paralysis can follow unilateral cortical lesions; and, so far as I am able to determine, we have no record of the occurrence of a vocal paralysis, resulting from nuclear or cortical lesions, that was not associated with

paralysis of other nerves situated close to the recurrent centers.

These statements warrant us in practically excluding cerebral lesions in determining the cause of unilateral vocal paralyses when unassociated with involvement of other nerves in the paralytic process. The pressure of an enlarged left auricle, causing left recurrent paralysis, must be distinguished from the pressure resulting from aneurysms, tumors, or adhesions. These do not produce intermittent paralysis of the recurrent laryngeal nerve, the condition where it has once supervened being permanent. Of course, if a mitral stenosis should become permanently incompetent and the auricle press continuously on the nerve, the paralysis would not differ from that due to the presence of a tumor, an aneurysm, adhesions, or any other permanent condition. However, it is reasonable to expect an incompetent heart to respond to treatment, and the recurrent paralysis should be expected to be intermittent if the mitral stenosis alone were responsible for its occurrence. Alexander's case and the case herewith reported are in accordance with this theory.

TWO CASES OF LOCOMOTOR ATAXIA IN MAN AND WIFE.

By E. STAEHLIN, M.D.,
NEWARK, N. J.

I WISH to report two cases which proved interesting to me because (*a*) of the indirect way in which I arrived at the diagnosis, and (*b*) because they are both directly traceable to syphilis as the etiological factor.

CASE I.—A man of about 46 years of age, married, presented himself, with the statement that there was something wrong with his urine. Investigation into the previous history revealed nothing, and the man professed good health in every respect.

The sample of urine, freshly passed, had the appearance of yellow paint—very thick, very offensive, opaque—and on examination was found to contain pus cells and triple phosphate crystals in abundance, and on standing the glass was three-fourths full of a thick, tenacious mucus. It was plain the man had cystitis, but the cause was not evident.

I could not account for the absence of bladder tenesmus in so marked a case of cystitis; the man could go twelve hours and feel no inclination to pass urine—a significant point, which I did not interpret at the time. Washing out the bladder was evidently in order, and on introducing a catheter (Nélaton No. 20), I met with an obstruction at the triangular ligament. A No. 12 passed into the bladder, when, to my surprise, a large quantity of residual urine of the character described was passed.

I considered the situation nearly solved, and that I was dealing with a cystitis, caused either by urethral stricture (at this stage he admitted having had gonorrhœa) or an enlarged prostate. The latter, however, was not found on digital examination.

The bladder was daily washed out with a weak solution of permanganate of potassium, alternating with the silver salts, and sounds were passed to dilate the stricture. In two weeks the patient was much improved; the urine looked like lemon juice; there was less mucus and fewer crystals of triple phosphates. The man had also been taking a urinary antiseptic. And so we continued for three weeks longer, with little or no change in the condition of the urine.

CASE II.—About this time a woman presented herself, the wife of the patient, claiming to have kidney trouble. Having been under treatment for three months with no relief, she decided to call on me. Her color indicated that she might have chronic diffuse nephritis. She complained of swelling of her feet, which was not discovered on examination, however. Examination of the urine gave negative results in repeated examinations, and the heart's action was normal. The blood showed a marked reduction in hæmoglobin and the presence of a few malaria plasmodea.

She was put on tonic treatment, and soon said she felt better, but insisted that her legs were swollen and heavy; œdema was, however, never found. One day, about two weeks after her first visit, in going down stairs she stumbled. There was no obstruction in the hall, and the woman volunteered the information that she recently stumbled even on smooth pavement. I recalled her, with the misgiving of having overlooked something, and examined her reflexes. The patellar reflex proved absent. I then examined her pupillary reaction, and found that her pupils did not react to light. Romberg's symptom (the swaying of the body while eyes are closed and feet placed close together) was pronounced. Fortified with these cardinal symptoms, I called for her husband and pronounced his wife's case one of locomotor ataxia. We had a very plain talk, in which he admitted that he contracted syphilis about ten years ago, and in spite of great care had infected his wife, and that she had passed through the successive stages of the disease. The husband, too, presented the cardinal symptoms of locomotor ataxia—absence of patellar reflex, Argyl-Roberts in pupil, and Romberg's symptom—all of which were overlooked, owing to the absence of subjective symptoms, excepting the bladder trouble. There was not even a semblance of ataxia.

Within a year the man has died of an intercurrent disease; the woman is steadily becoming worse and more ataxic.

Both claimed to have been subjected to antisyphilitic treatment for a period of two full years from the very week of secondary signs.

403 HIGH STREET.

Paraffin Injections for Overcoming Wrinkles and Minor Facial Imperfections.—Charles C. Miller explains that it is but seldom that the glabella is sufficiently undeveloped to permit of correction by the deposit of a considerable mass of paraffin. Consequently, the result must be attained in some other way. The paraffin should be placed as near the true skin as possible without placing it in this structure. In the case of a single line-like wrinkle on each side of the median line, or a single wrinkle only on one side, it can be corrected very often by placing a thin layer along immediately beneath the wrinkle. This will stiffen the tissues at the point where the wrinkle forms, and it will thus be overcome. In the case of several wrinkles well down between the brows, the condition can be corrected by placing the paraffin beneath the inner fourth of the eyebrow on each side, and in some cases a V-shaped deposit will secure a perfect result, one bar of the V extending along beneath the brow and the other obliquely upward and outward toward the frontal eminence. In certain cases in which there are a number of wrinkles extending well above the glabella, they can best be corrected by placing 3 or 4 delicate streaks of the drug across the site of the wrinkles. Aseptic precautions in all this work should be absolute. It is well to use a special syringe, which acts by a screw. A small needle is less painful than a large needle. When the paraffin has been deposited, the operator may mould it according to will. The punctures are sealed with sterile collodion. In some cases the result will be a failure, and there is no contra-indication to repeating the injection.—*The Cincinnati Lancet-Clinic.*

MEDICAL RECORD.

THORACIC SURGERY.

THE wave of progress which followed the practical application of the principles of asepis owed its importance in large measure to the new regions that were made accessible to the scalpel. This was especially the case with the abdominal cavity which had previously been *terra incognita,* but now proved to be a veritable Eldorado for its first surgical explorers. To-day there is hardly an organ below the diaphragm that cannot successfully be subjected to operative treatment, but this muscular septum has been in some measure a barrier to the further advance. Most thoracic diseases are still inaccessible to the hand of the surgeon, partly through their nature, though tumors, wounds, and hemorrhages occur here as in other regions, partly through the difficulties attending accurate diagnosis, for the ordinary methods of physical examination and even their latest adjunct the *x*-ray often give only presumptive evidence, but most especially through the physical conditions prevailing in the chest cavity. The physiological difference in pressure between the lung and the pleural cavity is disturbed as soon as air enters the latter, the lung collapses and pneumothorax with all its dangers is caused. The fact, established through experiment on animals and sad experience with man, that unilateral pneumothorax is dangerous and bilateral pneumothorax is almost inevitably fatal, has practically excluded operative work under conditions in which this casualty might have to be reckoned with.

Numerous suggestions have been made by different authors to overcome this difficulty but without satisfactory results, and though a few daring operators have recorded successful suture of the heart, pulmonary cavities have been drained, and even small portions of the lung resected, in the main the operations have been confined to pleural conditions such as empyema and the operators have striven to isolate the proposed field of manipulation either by preliminary injections of irritants to produce adhesions or by suture of the pleura before incising it.

For some time work has been done in the surgical clinic of v. Mikulicz and in the pharmacological institute of Filehne in Breslau, with a view to solving this problem, and Sauerbruch (*Mitteilungen a. d. Grenzgebieten d. Medizin u. Chirurgie,* Vol. 13. No. 3) now supplements several preliminary publications by an exhaustive résumé of what has been accomplished.

After an extensive series of observations on animals it was found that all sorts of artificial respiration, whether carried on through the larynx by means of apparatus similar to that of Fell-O'Dwyer or of Matas, or through a cannula inserted directly into the air passages after a preliminary tracheotomy, produced such serious circulatory and respiratory disturbances as to preclude their practical employment. It was further found that the dangers of pneumothorax were mainly due to the collapse of the lung, and this less on account of its functional restriction than owing to other effects accompanying its change in size (congestion, vagus reflex). In order to prevent this collapse the author enclosed the chest of the experiment animal in an air-tight chamber of glass and exhausted the air within slightly by means of an air pump. The hands, introduced through apertures in a rubber sheet stretched over one end of the cylinder, were free to perform the necessary manipulations within while the head of the animal remained outside. Under these conditions extensive operations involving the opening of both pleural cavities could be done without collapse of the lung or any marked circulatory or respiratory disturbance. This plan has been developed by degrees, until now a full sized pneumatic operating room for human subjects has been built and has been used by v. Mikulicz in operating on ten cases. The construction is of heavy sheet iron with large plate-glass windows and suitable means for keeping up a constant negative pressure of 10 mgs. of mercury, while at the same time fresh air is admitted continuously. The patient's body is within the cabinet but the head projects outside through an opening in the wall made to fit closely to the neck by means of a perforated curtain of rubber. Within the cabinet are electric light connections, telephone, water pipes, and the valves and gauges necessary for controlling the air apparatus. In order to avoid disturbing influences on the general circulation the patient's body below the waist is enclosed in a rubber bag communicating with the outer air. When the apparatus is working the entire chamber, with the operator and his assistants, becomes simply an extension of the patient's pleural cavity; as soon as this is opened collapse of the lung does not occur, and respiration proceeds normally. No inconvenience is experienced by those within the cabinet, for the decrease in pressure is no greater than that regularly existing at an altitude of three hundred meters. No details are given of the operations already performed, but these will no doubt soon follow and the surgical world will be enabled to judge of the possibilities of the method.

RECENT EXPERIENCES WITH GUNSHOT WOUNDS.

IN the *Journal of the Royal Army Medical Corps* for August Lieut.-Col. G. H. Younge analyzes 1,053 cases of rifle bullet wounds seen by him during the Boer War. As a rule, but far from invariably, the Mauser wounds were "humane." When the bullet came into contact with bone, however, the injuries were often very severe, extensive splintering not infrequently occurring, and occasionally portions of the shaft were blown clear away. The rapidity of healing of simple flesh wounds was often surprising. In ninety-two cases the wounds were of the head, and, with few exceptions, perforating. In several cases the bullets traversed the brain without produc-

ing any immediate symptoms. In two cases cited there was no unconsciousness, and, besides the wound itself, effusion of blood into the orbit, with consequent protrusion of the eye, was the only thing noticeable.

Penetrating wounds of the chest were noted in eighty-five cases. In the fatal cases death ensued rapidly from internal hemorrhage. This danger once escaped, recovery took place often with wonderful rapidity. The symptoms and the gravity of the cases depended largely on the proximity of the wound to the root of the lung. When the apex or the outer section was alone involved, the symptoms were often quite negative. As a rule, dyspnœa was not a prominent symptom, and in the absence of hemorrhage into the pleura, was of short duration, or even entirely absent. Hæmoptysis was often altogether absent, and when present was generally slight and of short duration. Superficial emphysema was very rare, being marked in only one case. Hæmothorax was also exceptional, being indicated when present by rapidly increasing dulness and loss of vocal resonance. One man with a Mauser wound through the heart lived more than a week.

Wounds of the abdomen occurred sixty-six times. Of these twelve were rapidly fatal from shock, and two from hemorrhage. In the rest hemorrhage was absent or too slight to be detected by physical examination. When the intestines were perforated, blood as a rule passed per anum, usually in small amount. Its absence, however, did not exclude intestinal injury. No case showed protrusion of viscera or escape of fæces or of flatus through the wound, owing, no doubt, to the small Mauser aperture. That a bullet could pass through the abdomen without fatal injury was opposed to all previous experience, but in the Boer War recovery from such wounds under simple expectant treatment was by no means uncommon. The general experience of the campaign showed that laparotomy is applicable in the field only under rare and special circumstances. Younge gives his impressions as to the proper surgical handling of these cases, speaking with special reference, of course, to the conditions of military surgery. If a bullet passes through the epigastric or umbilical regions and the symptoms justify a diagnosis of perforation of the stomach or small intestines, operation is urgently demanded, provided the patient can thereafter be immediately transferred to a stationary hospital. If, however, as occurs in most battles, six or eight hours have elapsed, laparotomy is more apt to hasten death than to relieve. In wounds of the splenic region, with symptoms of steadily increasing internal hemorrhage, immediate laparotomy offers probably the only chance. In those of the hypogastric region, involving the bladder, the conditions in each case must govern. If the exit wound is large enough and so situated as to allow of drainage of urine, the wound should be allowed to heal by granulation, but if urine accumulates in the peritoneal cavity the patient cannot escape without operation. On the other hand, in bullet wounds of the lateral abdominal regions, involving the ascending or the descending colon, the liver, or the kidneys, operation is not usually called for, as many, if not most, of these cases do well under expectant treatment.

The treatment at the field hospital consisted in immediate examination and a cleansing of the wound with bichloride (1:1000), if necessary; the first field dressings were left alone in simple flesh wounds, when the dressings were found clean and undisturbed. The wounds were then dusted with iodoform, covered with a thick layer of boric or salicylic wool, and firmly bandaged. Bullets deeply imbedded were left for future removal. Hemorrhage was usually absent, but occasionally ligature of an artery was necessary. Fractures were carefully put up in extemporized splints. The uniform rule was to perform no operation not absolutely necessary for immediate safety. The result was that many limbs were saved when at first sight such a result seemed impossible. Only eight amputations were performed (four major and four minor). In some gunshot wounds of the lung, with hemorrhage, ergotin was given hypodermically with apparent benefit. Morphine hypodermically was given freely, and apparently with the best results. Younge says that he looks upon morphine as more or less a necessity in severe and painful gunshot wounds, for it relieves pain, diminishes the risks of shock, and has a beneficial action on the wounds. In cases of abdominal wounds it was given freely, and was the main item in the treatment.

A point of interest and importance was that of the large number of wounded, many of them very severely and with lacerated wounds often fouled by earth and other septic material, no case of sepsis or tetanus occurred. Considering that in the Crimean War three out of every five deaths after operation were due to septicæmia, these results are gratifying. The death rate at the field hospital was 3.3 per cent., which included all the men who had left the field alive, some of whom, however, were dead upon reaching hospital.

Sir Felix Semon.

The eminent exponent of laryngology, whose paper on cancer of the larynx in the present issue of the Medical Record will read with interest and profit, is, in his many-sided character, among the most noted, and deservedly so, of those who follow that specialty to-day. A pupil of Sir Morell Mackenzie, Sir Felix Semon was a contemporary with the pioneers in laryngology in the old world and a companion of those in the new, being, we believe, the oldest corresponding member of the American Laryngological Association, itself the first of the national societies devoted to a study of that branch of medicine. As such he has been warmly welcomed by his confrères in this country, and has been entertained by individuals and societies in all the large cities of eastern America, from New York to St. Louis and from Washington to Chicago and Montreal. But he has won distinction not only as a practising laryngologist but as a medical editor as well. A type among special journals and one to serve as an example for all others of its kind is the *Internationales Centralblatt für Laryngologie,* founded and raised to its present commanding position by the editorial skill of Sir Felix Semon. No advance in this specialty has been made in any part of the world since the foundation of the journal that is not there chronicled, and no one who would inform himself on any subject connected with the study of the upper air-passages can fail to find the information he desires in the files of this periodical.

Progeria; A Form of Senilism.

Under the designation of progeria Hastings Gilford (*Practitioner,* August, 1904) describes a condition in which the degenerative processes that constitute the state of senility occur prematurely and are morbidly accelerated. He reports two well-defined cases of the affection, and a third of less pronounced character. In all three the disorder began without evident cause and was characterized by a curious mixture of immature development on the one hand and premature old age on the other. Death resulted, apparently from senile decay, at the ages of 17, 18, and 43 years, respectively. In the two more pronounced cases the patients were like children in stature, although in other respects they looked like old men. They were lean, weak, decrepit, and bald, with the exception of a sparse growth of gray or colorless hair. The skin was dry, wrinkled, and wasted, and it did not conceal the underlying tendons and veins. The patients seemed to be somewhat precocious in intelligence, but a few years behind their age in sexual development.

In the skiagrams the shafts of the long bones were seen to be thin and delicate, their ends thick, and the fusion of the epiphyses a little premature. The same mixture of youth and old age was found to characterize the various internal organs in one case in which a post-mortem examination was made. The liver was large and healthy, the kidneys and adrenal bodies were slightly degenerated. The brain was healthy, but the stomach and intestines were of paper-like tenuity. The thymus gland was persistent, but degenerated, while the thyroid, pituitary, and pineal bodies appeared to be healthy. Some of the lymphatic structures were normal, while others were wasted. The coronary arteries, the aorta, and the valves of the left side of the heart were markedly atheromatous and the seat of calcareous degeneration.

Ignored Syphilis.

Dr. C. F. Marshall writes in *Treatment* for September 1904, on the futility of inquiring for a history of syphilis. He quotes largely from Fournier's views on the subject of ignored syphilis. Fournier gives the following chief causes for ignored syphilis: (1) Benign Secondaries. The chancre may be small or simply an erosion, the roscola may be transient, and the buccal erosions mistaken for aphthæ. Nothing further may occur till tertiary manifestations occur. (2) Extragenital Contagion. Syphilis may be conveyed by the barber's brush, by pipes and drinking utensils, by the water-closet, by tattooing, and by domestic and professional contamination. (3) Ignorance. Certain women are absolutely ignorant of venereal disease. (4) Medical Dissimulation. This is a common cause of ignored syphilis. For instance, a married man infects his wife with syphilis, and implores the doctor to keep the matter secret for the sake of avoiding scandal, and perhaps the breaking up of a hitherto happy domestic hearth. The doctor finally acquiesces, and the patient is treated without being informed of the nature of her malady. If, later on, symptoms of syphilis appear, and the wife consults another physician, she will naturally deny having had syphilis, if the doctor is bold enough to ask the question.

Fournier estimates the frequency of ignored syphilis at 3 per cent. in men and 18 per cent. in women. Hence it is six times more frequent in women than in men. These figures result from statistics based on 4,257 cases of tertiary syphilis, of which 3,862 occurred in men and 395 in women. Out of these there were 120 cases of ignored syphilis in men and seventy-one in women. From these figures we get the percentage of 3.1 in men and 17.9 in women.

Dr. Marshall therefore concludes that inquiry into a history of syphilis is frequently a waste of time, and that the acceptance of statements on this point made by patients is detrimental to the patient and to the reputation of the doctor.

Medical Military Attachés.

Military attachés, and to a lesser extent naval attachés, are recognized as a more or less necessary means for the various nations to keep in touch with the latest phases of warfare. In all wars between large countries military attachés are appointed by the several governments to the different armies in the field to watch the course of events and to report thereon. In this manner the latest developments of the science of war are carefully noted by experts, so that the knowledge gained may in the case of need be employed to the best advantage. It would appear that there should be plenty of scope for the services of medical military and naval attachés in a struggle like that, for instance, now being waged in the far East; yet it was only a few days ago that the Army General Staff decided to dispatch American army surgeons and attachés to the Japanese and Russian armies in the far East, provided the consent of the authorities can be secured.

The field is, so to speak, practically unlimited. In a long-continued war, especially under the climatic and sanitary conditions prevailing in Asia, diseases of all kinds will abound. For the study of typhoid fever, dysentery and diarrheal affections, cholera, and perhaps bubonic plague and beriberi, the opportunities must be unique. Much was learned concerning typhoid fever in the Spanish-American and Boer wars, but the present war offers a far more extended range of observation. So far as preventive medicine is concerned, the facilities for gaining knowledge in a thoroughly practical way are obviously unequaled. The value of medical naval and military attachés from a surgical point of view needs no comment. Much has been learned in recent wars concerning the effects of wounds produced by the modern excessively swift small-bore bullet, and by modern artillery. The war in the far East presents an infinitely wider opportunity in this respect. The perfection of the Japanese medical organization, moreover, has won world-wide admiration, and it is not only a matter of surprise that this country has been so slow to make use of the opportunities for observation afforded, but it is to be regretted that even now but one surgeon is to be detailed to each army.

Nasal Suppuration.—J. Mackie submits the following propositions: (1) That the essential cause of nasal suppuration is defective drainage. (2) That defective drainage is mainly due in childhood to adenoids and lymphoid hyperplasias. (3) That later it is the result of hypertrophies and deformities resulting from lymphoid hyperplasias during the period of active growth and development. (4) That by adopting this view of the natural history of nasal suppuration the whole subject becomes more intelligible, and a simpler and more rational treatment becomes possible. Acting on these principles, he declares that in many cases of sinus disease the removal of a portion of the middle turbinal will afford proper drainage to the various sinuses and render many of the so-called "radical" operations unnecessary. He believes that the ethmoidal cells are the most frequent seat of sinus suppuration. Cases illustrative of the truth of his contentions are given.—*Journal of Laryngology.*

News of the Week.

A Dinner to Sir Felix Semon was given at Delmonico's on Tuesday evening of this week by the Laryngological Section of the New York Academy of Medicine. Over one hundred members of the Section and of the American Laryngological Association and invited guests were present. Addresses of welcome were made by Dr. Francis J. Quinlan, Chairman of the Section, Dr. Andrew H. Smith, President of the Academy of Medicine, and Drs. George M. Lefferts, Clarence C. Rice, William Kelly Simpson, and Emil Mayer, and were responded to by the distinguished guest of the evening. On the following evening an adjourned meeting of the Laryngological Section of the Academy was held, at which Sir Felix read the paper on "Cancer of the Larynx" published in this issue of the MEDICAL RECORD. On Thursday afternoon he delivered a lecture on "Acute Septic Inflammations of the Throat and Neck" before the senior class of the Long Island College Hospital in the Polhemus Clinic, corner of Henry and Amity streets, Brooklyn.

Prize Awarded at St. Louis to Dr. Baruch.—The Superior Jury of Awards of the Louisiana Purchase Exposition has awarded a silver medal to Dr. Simon Baruch, of this city, for his exhibit, consisting of drawings, plans of construction, and explanatory texts and statistics showing the economic value of free cleansing baths, the cost of construction and maintenance, etc. The object of the exhibit was to impress upon sanitary authorities of the various municipalities the importance of free cleansing baths, offering ample facilities for personal cleanliness to the working people. This idea was first broached by Dr. Baruch fourteen years ago, and after seven years of propaganda the first free baths in this city were opened in Rivington Street in 1897. New York has now a number of such baths, and Chicago has five. In recognition of Dr. Baruch's work one of the new free public baths in Chicago has been called "The Simon Baruch Bath." There is no other country in the world in which a bath with soap and warm water can be had by any one without cost; but that is not the fault of Dr. Baruch, for he had an exhibit at the Paris Exposition in 1900, similar to that at St. Louis, which was awarded a silver medal and diploma.

Honorary Degrees from Columbia.—During the celebration of the one hundred and fiftieth anniversary of the foundation of Columbia University the following medical men received honorary degrees: *Doctor of Laws*, Drs. Edward Gamaliel Janeway, Francis Delafield, William Mecklenburg Polk, John Green Curtis, William Henry Welch, and Walter Belknap James; *Doctor of Science*, Drs. William Stewart Halsted, Moses Allen Starr, Luther Emmett Holt, and George Sumner Huntington.

Medical License Requirements in Illinois.—A resolution was adopted at the October meeting of the Illinois State Board of Health amending the rules of the State Board of Health adopted July 11, 1899, relative to the character of examinations, as follows: On and after January 1, 1905, the Illinois State Board of Health will accept as an equivalent of a part of the examination required satisfactory evidence of five or more years of reputable practice of medicine and surgery since graduation, and will allow a credit of five per cent. on the required average of seventy-five per cent. for each period of five years of such practice on the part of a candidate for a certificate.

The Fourth Pan-American Medical Congress, as we have before noted, convenes in Panama the first week in January next. The delegates will leave this country by the Atlantic, Pacific, and Gulf Coasts the last week in December. They can return by the same ruotes, or make round trips. The Public Health Association meeting will take place the following week in Havana, and those desirous of attending both meetings can arrange to do so.

There are two routes for the physicians to take from Panama to Havana. The first is by way of Jamaica to Santiago de Cuba by boat and overland by rail to Havana. The second is by water from Panama to Vera Cruz and thence to Havana. From Havana, the return trip can be made directly north to New York by water or via Miami or Tampa, Florida, or New Orleans. The connections and dates of sailing are now being arranged. The Panama Government has appropriated $25,000 for the Scientific Session and the entertainments. The Congess will be held from the second to the sixth of January. The afternoons will be devoted to the Scientific Sessions and the mornings and evenings to trips and social functions. So far as can be learned, the program in Panama will be a reception on the first day by President Amador, and the formal opening session of the Congress the same evening. On the second day, an excursion to the Canal in the morning, meeting of the various sections in the afternoon, and a banquet in the evening. On the third day, an excursion down the Bay to Taboga Island, where a Panama breakfast will be served, scientific sessions in the afternoon, and a ball in the evening. On the fourth day, an excursion to the U. S. Army barracks in the morning, section meetings in the afternoon, and the formal closing session in the evening. On the fifth day, an excursion to the plantation of the United Fruit Company; and on the afternoon of this day, those who intend going to Cuba by way of Jamaica to attend the meeting of the Public Health Association, will sail for Kingston, while those who intend going by way of Vera Cruz, or returning home by way of New Orleans or New York, will remain until the following Tuesday. The Secretaries of the Sections of the Congress for the United States are Drs. A. H. Doty, of New York, Hygiene and Quarantine; Judson Daland, of Philadelphia, Medicine; R. Matas, of New Orleans, General Surgery; Bert Ellis, of Los Angeles, Eye; Hudson Makuen, of Philadelphia, Throat; Frederick Jack, of Boston, Ear; C. H. Hughes, of St. Louis, Nervous Diseases; George Goodfellow, of San Francisco, Military Surgery; H. P. Newman, of Chicago, Gynecology; John Ridlon, of Chicago, Orthopedic Surgery; D. W. Montgomery, of San Francisco, Dermatology; C. G. Kerley, of New York, Pediatrics; Noble P. Barnes, of Washington, Therapeutics; Walter Chase, of Boston, Pathology; E. G. Zinke, of Cincinnati, Obstetrics. Communications from physicians in the United States interested in any one of these branches can be sent directly to the respective Secretaries. Delegates intending to attend the Congress, desirous of obtaining information concerning it, should communicate with the Secretary of the International Executive Committee in the United States, Dr. Ramon Guiteras, 75 West Fifty-fifth Street, New York City.

Action Taken Against Club Practice.—At a recent meeting of the Fulton County (N. Y.) Medical Society an amendment to the by-laws was unanimously adopted forbidding the members to practise for clubs at cut-rate prices. The by-law provides that "on and after the first day of January, 1905, no member of the society shall accept the position of club, society, or organization physician, or agree, or continue to do any medical or surgical work for any club, society, or organization at a less rate than the

regular or customary charges for like services rendered by other physicians for patients not members of such club, society, or organization." The by-law does not forbid the taking of a smaller fee than customary in proper cases, and exception is also made in the case of any one acting as city, county, or town physician or health officer. Any violation of the by-law is to be considered unprofessional conduct and render the guilty member liable to suspension or expulsion, as the society may determine.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1905, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in Medicine, but cannot have been published, and must be received by the Secretary of the College, Dr. Thomas R. Neilson, on or before May 1, 1905. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1904 was not awarded, no essay of sufficient merit, in the judgment of the committee, having been submitted in competition.

Free Distribution of Milk in St. Louis.—Pure milk stations for the free distribution of pure milk to the poor in St. Louis was discontinued on November 1. The use of pure milk during the summer demonstrated that the mortality rate in children under five years could be reduced by furnishing pure milk. In 1903 there were 404 deaths of infants under five years, while in 1904 the number of deaths was 236. This includes all causes. The deaths from causes over which the use of pure milk would have an influence were 123 in July, 1903, and 92 in July, 1904. In addition to furnishing pure milk to the poor the health department exercised great vigilance over milk peddlers and prosecuted a number for selling impure milk.

Smallpox in Illinois.—Carelessness as to vaccination and other sanitary precautions brought about by the mild type of the disease and the decrease in the number of cases during the last year is responsible for the present epidemic of smallpox, according to the latest bulletin of the Board. The bulletin issued to local health authorities says that, as foretold by the State Board of Health in its warnings, the virulent type of smallpox has returned. During the month of September, in one infected district, ten patients among fifty afflicted died in a period of four days, one death in every five. In another, twenty-five among two hundred, one death in every eight. During August a few cases of smallpox, improperly diagnosed as some harmless disease, were found in a certain town in Illinois. No precautions were taken to prevent contagion. Vaccination was neglected. In a few weeks contagion had spread into five adjoining counties, and the malignant type of the disease appeared. Panic reigned; travelers avoided the town, and business was practically suspended. Human lives were sacrificed to pay for the failure of the local authorities to appreciate and act upon the repeated warnings of the State Board of Health. The Board urges that every effort be made to induce managers and owners of manufacturing and other plants or establishments employing large numbers of persons to unite in a determined fight against the disease, by insisting upon evidence of satisfactory vaccination of every employe.

Chicago Gynecological Society.—This society recently held its annual meeting, when the officers elected for the ensuing year were as follows: *President*, Dr. J. Clarence Webster; *Vice-Presidents*, Drs. Frank T. Andrews and Henry F. Lewis; *Secretary*, Dr. Palmer Findley; *Editor*, Dr. Rudolph W. Holmes; *Treasurer*, Dr. Charles B. Reed; *Pathologist*, Dr. Gustav Kolischer; *Councilor*, Dr. Emil Ries.

The Medical Colleges of California all opened with large classes. In several of them the attendance is from 25 to 50 per cent. greater than in previous years, and an unusually large part of the classes is made up of young men from the East.

Dr. H. N. Rucker, former superintendent of the insane asylum at Stockton, Cal., has been appointed to the superintendency of the Masonic Home at Decoto, to succeed Dr. Aiken, recently resigned.

Yellow Fever in Mexico.—There are six new cases of yellow fever at Texistepe. There are in all twenty-four patients. The last patient has left the hospital at Tehuantepec, but Merida reports two new cases, and Salina Cruz four new cases.

Diphtheria at the Navy Yard.—Diphtheria has broken out in the marine barracks at the Brooklyn Navy Yard. Most of the cases are in a mild form, but the condition of one man is said to be serious. All of the sick men are in the Naval Hospital.

Generosity Urged for Medical Colleges.—At the meeting of the New York University Council, Chancellor McCracken in his annual report pointed out the indifference of wealthy men to the needs of medical institutions. "What is the matter with New York in its treatment of medicine?" he asked. "I have observed the situation for twenty years, and can find no word to express it better than disgraceful. The disgrace attaches to the wealthy men of New York. I can count on my fingers every large giver to medicine in New York in the last twenty years."

Discriminating Against the Tuberculous in Denver.—According to a newspaper report consumptives are hereafter to be barred from the positions of letter carrier and postal clerk in the Denver Post Office. A special order to that effect was received there last week.

Remarkable Action of the Police.—The police of Lancashire have presented to the townships over which they have jurisdiction forty-six handsome ambulances, many of them costing $500. The money was raised by means of football matches and other athletic sports.

Awards for Charity Exhibits.—The International Jury of Awards at the St. Louis Exposition has awarded two grand prizes to the Charity Organization Society of the City of New York—one for its general exhibit, and another for the special exhibit prepared by the Committee on the Prevention of Tuberculosis. Several of the workers in the society also received personal awards as collaborators, or in recognition of special services in some field of philanthropic activity.

A Doctors' Race.—An amusing feature of the closing day of the North Georgia Fair held at Chickamauga in the third week of October was a "doctors' race." The twelve physicians who took part in the contest had their horses stabled nearby and were themselves undressed and in bed. At the stroke of

the gong they had to dress, hitch their horses to their vehicles, and drive one mile to a supposed patient. The race was won by Dr. Rudesell. Dr. Elder was second and Dr. Hunter third.

A Threatened Epidemic Among Texas Cattle.—Alarm is felt among cattle rangers over a fatal disease that has appeared in several North Texas communities. The death of more than two hundred head of cattle has been reported, the sickness being aggravated by the heavy rains and cold weather.

Condensed Milk of Poor Grade.—The State Commissioner of Agriculture is to take action against the manufacturers of certain inferior grades of condensed milk which have been discovered on sale in this city. Standard condensed milk should have about 9 per cent. of butter fat and 28 per cent. of milk solids. Most of the stuff complained of has 1 per cent., or even less, of butter fats, and the percentage of solids varies from 10 to 20. Most, if not all, of the low-grade milk, it is said, is made outside of this State.

In Memory of Dr. N. S. Davis.—Eulogistic speeches and words in sympathy with his great life work were listened to by more than a thousand persons gathered at Powers' Theatre, Chicago, on Sunday afternoon, October 23, at the memorial meeting for the late Dr. N. S. Davis. The principal speakers were Bishop John Lancaster Spalding, of Peoria, Illinois, and Bishop S. M. Merrill, of Chicago. Dr. John B. Murphy, President of the Chicago Medical Society, presided. Short addresses were also made by Drs. Frank Billings and John H. Hollister. In view of Dr. Davis' work in Chicago, the South Park Commissioners have named a park in his honor at Forty-fourth street, Forty-fifth street, Marshfield and Hermitage avenues, known as Davis Square.

Obituary Notes.—Dr. O. S. Belden died at Camden, N. J., on October 26, at the age of 70 years. He was a veteran of the Civil War, and served as surgeon in the Fifth New Jersey Volunteers.

Dr. Frederick Shade, of St. Louis, died on October 18 of heart disease. He was a graduate of the University of Tübingen, Germany, in 1852, and had retired from active practice, although he continued to give attention to the sick poor without charge. He was 79 years of age, and at one time was very wealthy, but spent most of his money in charitable undertakings.

Dr. Franklin S. Whaley died recently at Compton, Cal., aged 85. He was born at Lockport, N. Y., May 8, 1819, sixteen days before the birth of Queen Victoria, a distinction of which he spoke with increasing pride in his old age. He came to San José in 1852 and engaged in practice there until 1870, when he removed to Compton. He retired from active practice about ten years ago on account of the infirmities of age.

Dr. Thos. F. Prewitt of St. Louis, Mo., died at his home on October 18. He was seventy-two years old at the time of his death and had retired from practice two years previously. He was graduated from the St. Louis Medical College in 1856. For twenty-five years he was chief surgeon of the St. John's Hospital and was Dean of the Missouri Medical College, and later professor of the principles and practice of surgery in the Medical Department of Washington University. He served as president of the Missouri State Medical Association and of the American Surgical Association.

Dr. Edwin E. Webster died at his home in St. Louis on October 27 from senility. He was graduated from the St. Louis Medical College in 1856, and was eighty-two years old. For twenty-seven years he was physician to the Old Ladies' Home and was well known among the poor for his charities.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE VISIT OF FRENCH DOCTORS TO LONDON—INSPECTION OF HOSPITALS AND SCIENTIFIC INSTITUTIONS—ENTERTAINMENTS, WELCOME, FAREWELL—ITEMS.

London, October 14, 1904.

Our French guests arrived in London on Sunday evening and have occupied most of our attention up to Wednesday evening, when they were entertained at the dinner. About thirty of them brought their wives, and to entertain these ladies a committee of London doctors' wives was formed, to whom the French physicians expressed their most cordial thanks. The number of our visitors has exceeded our expectations, but we have done our best to show them our institutions and make the occasion one to be remembered with pleasure. On arrival they were met by the executive committee and conducted to the Hotel Russell, where they were received as guests in the most informal manner. Leaders of French and English medicine met and chatted together with the free-masonry of the profession. The visitors selected the institutions they wished to inspect and lists were prepared in readiness to facilitate their choice.

At 10 a.m. on Monday the visitors were received at the Royal College of Surgeons by the President, Mr. John Tweedy, who wore his robes of scarlet and violet, braided in gold, and a doctor's cap. With him were the vice-presidents, Messrs. Robson and Butlin, also in robes, and a number of the council. A procession, preceded by the mace, was formed, and Mr. Tweedy made a brief speech in French, welcoming the French guests as of one family with their British colleagues, the family of Asklepios, and also the successors of Hippokrates, Galenos, Paré, Bichat, Harvey, and of John Hunter, whose genius was associated with the college and great collection they were about to enter. Dr. Lucas Championnière spoke in acknowledgment, and the party distributed themselves in the museum, chaperoned by specialists in various sections. Afterwards some went to King's College Hospital and others to Charing Cross Hospital. About fifty went to St. Bartholomew's, and were received by the staff and the president of the Royal College of Physicians, Sir W. Church, who is on the consulting staff. Other groups went to the National Hospital for the Paralyzed and Epileptics, to the Royal Free Hospital, and other medical institutions. The *Lancet* gave a luncheon, at which about seventy English and French doctors met and interchanged many compliments. In the evening a reception was given by Dr. Dundas Grant.

Early on Tuesday our guests set off on further explorations. About eighty went to the French hospital, where Dr. Triboulet expressed their pleasure in visiting a hospital which to many sick, poor Frenchmen must seem like a corner of their own beloved country. He further expressed the thanks of his colleagues to the staff of "those Anglo-French physicians," and said what they had seen showed that they must delete the words "perfide Albion" from their vocabularies.

At St. Mary's Hospital Dr. A. E. Wright, speaking in French, gave an account of the treatment of tuberculosis and staphylococcus invasion by inoculations with the corresponding bacterial vaccines. He showed some cases which, he said, appeared to be almost hopeless before being submitted to the treatment.

At Queen Charlotte's Lying-in-Hospital another group examined the wards, the pathological laboratory, and the arrangements for sterilization.

The greater number went to see the laboratories of the university founded two years ago. The leading physiologists teaching in London had then agreed to give gratuitous courses of lectures, chiefly on the subjects they had personally investigated. In the first fifteen months twenty students had carried on researches here, which had resulted in twenty-three communications to scientific journals. Botanists and zoölogists are following this example, and the principal, Sir A. Rücker, takes it as a hopeful sign that the more popular educational work is thus being supplemented by masters of science dealing with its highest aims.

Dr. Waller pointed out the various departments directing special attention to the electro-physiological section, and showing his apparatus for administering chloroform.

At noon a luncheon was given by the dean of the faculty of medicine, to 230 guests—quite an international assembly. The usual toasts were honored. In replying to "Our Guests," Professor Poirier said he and his colleagues were struck by the results of individual and collective initiative, as shown in the institutions visited. In France they were under the tutelage of the state and, without comparing the two systems, they must admit that Republican France could learn something from Monarchial Britain. French-

men always called Englishmen phlegmatic and stiff. Phlegmatic they were, but not stiff, as witnessed the sympathetic reception given by them to their visitors. Might their collaboration in science help to secure peace, health, and happiness. The speech elicited great applause.

In the afternoon groups visited more hospitals—Guy's, St. Thomas's, Middlesex, where the cancer wards and the chart of cases treated since 1746 elicited great interest, the Samaritan, West London, St. Mark's, and one or two others. In each the lions of the place were shown by the staff and officials, and great satisfaction was generally expressed by the visitors.

One thing we exhibited on this day that we would fain have hidden from our French friends—a London fog. It was not one of our worst, but rather bad. A few brave Frenchmen were undeterred by it from their project to see one of the largest of our poor law infirmaries—that at Highgate, which is one of the newest and equipped with all modern appliances. It gave them the opportunity of contrasting our voluntary and state-supported hospitals, though I doubt if they all appreciated the difference between the two systems.

On Wednesday we had more favorable weather to show our visitors—clear, crisp, as becomes October—so they can dispel the fable that we are always in a fog. They resumed their visits to the hospitals with ardor. About forty at different times went to King Edward VII. Hospital for Sick and Wounded Officers. This institution has a brief but remarkable history, and as I have not previously said much about it, may now tell you that it was founded in the first year of the South African War, by Miss Keyser, in her own residence, at Grosvenor Gardens. She acted as matron herself, had five nurses, and has ever since maintained her hospital with only the help of personal friends. The visitors expressed no little surprise that a private house, while retaining all its amenities, had been converted into such a complete hospital.

The Imperial Cancer Laboratory, on the Embankment, attracted a considerable number. Many objects had been prepared for their inspection—specimens of cancer in mice and in fish, with microscopic sections illustrating the growth of cancer and the extent of the disease in the animal kingdom.

The Lister Institute, which owes its origin to Pasteur, naturally attracted a goodly group.

A number of gynecologists were over to the Chelsea Hospital for Women, where the operating theater and sterilizing rooms were greatly improved by the alterations only completed as late as August last.

A group of thirty alienists were entertained by the County Council at the splendid asylum at Clabury, which has accommodation for 2,450 lunatics, conveyances meeting them at Woodford station. Dr. Mott, pathologist to the council, was present and conducted the visitors over the laboratory, in which he has done such important work. It has been specially built for its purpose, and stands apart from the main building. Many preparations were shown, including some from cases of sleeping sickness. Luncheon was provided, and in response to the welcome, Professor P. Marie declared the satisfaction of his colleagues at seeing so magnificent an institution, and, as to their reception everywhere, it showed that they all belonged to the same great medical family. A drive through Epping forest afforded another form of entertainment, and the guests were taken back to the station.

A large number went to the London Hospital, where the light department and the Finsen lamps, presented by the Queen, attracted much attention.

In the evening came the concluding banquet, at which about 400 sat down. At the opening a message was received from the King, expressing the great satisfaction he had felt in noticing the arrival of so many French medical visitors to inspect the London hospitals, and the success of the visit, adding that he remembers with great pleasure that on the occasion of the International Medical Congress he had an opportunity of making the acquaintance of their distinguished countryman, the late M. Pasteur." The visitors heartily applauded, a suitable reply was framed and despatched, and the incident greeted with a hearty "Banc."

The dinner was a great success. The first toasts were the King and President Loubet, the National Anthem and the Marseillaise being heartily sung. The other speeches on both sides I must pass by, but may say when "Welcome" and "Au revoir" was proposed, the guests shouted "A Paris."

While the feast was going on the English hostesses entertained the French ladies and after dinner took them to the Alhambra to see the ballet, "L'Entente Cordiale."

The King has consented to lay the foundation stone of the new King's College Hospital, and will be accompanied by the Queen on the occasion.

The King has also consented to give his patronage to the Sanitary Institute.

I gave you a fortnight ago some account of the institute's exhibition.

Sir Dyce Duckworth has been appointed medical referee to the treasury and adviser to the Pensions' Board, *vice* Dr. Lionel Beale, F.R.S., resigned.

The new operating theater at the National Hospital was duly opened by the Duchess of Albany, on Saturday.

Our societies are gradually getting to work. The medical held its annual meeting on Monday. The medico-chi will begin its one hundredth session on the 25th, and later on it is intended to celebrate its centenary.

Lieut.-Col. G. Ryan, R.A.M.C., died on Saturday last, aged 59. He entered the medical service of the army in 1868, and retired in 1889. He served in the Zulu war of 1879, for which he had the medal.

OUR LETTER FROM THE PHILIPPINES.

INSECTS AS PLAGUE CARRIERS—HEALTH CONDITIONS—QUARANTINE AND INFECTED FOOD SUPPLIES—SYSTEMATIC VACCINATION.

MANILA, P. I., September 14, 1904.

At the September meeting of the Manila Medical Society a paper was read by Maximillian Herzog, of the Government Laboratory, entitled "Insects as Plague Carriers." After reviewing the literature on the subject, which, he stated, was rather negative with regard to the transmission of the disease in this manner, he gave a brief review of his own work in this direction. He stated that after much difficulty about one hundred fleas were collected at different times from rats caught in Manila. The plan was to starve them for four or five hours and then apply them under a cover of glass to his own skin. In no instance could the fleas be induced to bite him, and he came to the conclusion that the fleas found on Manila rats do not bite man. At the plague autopsies which he performed during the past year it was possible in almost every instance to trace the point of entrance of the infection, but in no instance could he recollect that the wound of entrance had resembled the lesion which is produced by an insect bite. On one cadaver he found some live head lice. These were captured, placed in a test tube, and subsequently ground up, and this substance inoculated into bouillon. Numerous colonies of bacteria developed, but the plague bacilli were finally isolated in pure culture. An attempt was also made to infect guinea pigs with plague by permitting fleas to feed upon plague-stricken rats and then to place them upon the shaved surface on the back of the guinea pigs, but these experiments were all negative. In concluding he expressed the opinion that fleas, if at all, were only remotely concerned in the transmission of plague. In the discussion which resulted one of the speakers said that in a number of experiments made with the fleas of Manila rats it was found that the fleas were not all of the same variety, and that on one occasion one of the rarer forms of the experimental fleas had bitten one of the laboratory attendants. The point was also made that, while the flea theory had not been scientifically demonstrated, yet it explained the transmission of plague in a greater number of instances than any hypothesis which had yet been advanced.

The Philippines are probably more free at present from the major contagious diseases than for any period during the past five years, but it is also probably true that at no time since the American occupation have the islands been threatened by the entrance of quarantinable disease from so many quarters. Plague has been present in epidemic form in Formosa to the north and in a lesser degree in Australia to the south. Cholera has made its appearance in China to the west. Smallpox has been very severe in the southern portion of Japan and in the vicinity of Shanghai, China. It will, therefore, be observed that the islands have been nearly surrounded by countries in which quarantinable diseases exist. The cholera has gradually spread north from Saigon until it reached the cities of Hanoi, Hong Kong, Shanghai, and Kobe. It is probably present in many more of the adjacent ports, and no doubt prevails more extensively than is generally reported. The islands are almost absolutely dependent upon outside sources for their food supply, and, strange as it may seem, this is particularly true with regard to fresh vegetables. This, in connection with the fact that the business of the islands is largely maritime, and anything that interferes with shipping at once becomes a serious economic question, makes it imperative that the means of communication with the outside have as few restrictions placed upon them as possible. Bearing the foregoing facts in mind, it will be seen that it is a difficult matter to prevent the introduction of infected food supplies. Another interesting question raised by the presence of cholera in China was, whether it was after all a real menace to the Philippines. The cholera was present in the islands for two years in epidemic form, and true to its former history it disappeared during the third year. Did it disappear because all the available material was used up, or did it disappear because the cholera

organism became so attenuated that it was no longer capable of conveying the disease? If the former was the case the Philippines were not seriously threatened, even if the cholera should have eluded the quarantine officials. If the latter was the case, however, another epidemic might have been started by the introduction of infected material. The quarantine authorities in the absence of definite information to the contrary adopted the latter view, and so far they have been successful in preventing its introduction.

The Board of Health is proceeding with the task of vaccinating the 7,000,000 or more inhabitants in a systematic manner. In June the work was commenced in the city of Manila. The city has been divided into districts. A large corps of vaccinators is concentrated in one of these sections at a time. Those in which smallpox has been more or less continuously present for many years have received first attention. Another striking argument in favor of vaccination has been revealed by the results in one of the worst of these districts, and one in which smallpox has been reported weekly for a long period. Since the completion of the vaccination over a month ago not a single case of smallpox has been reported, nor could any be found by the house-to-house inspection which was made. One case was found in a child which had not been vaccinated, and in which there is every reason to believe that the child had been taken into the district within the incubation period of the disease. Results of this kind are considered conclusive by even the more ignorant part of the population. The Board of Health has been very fortunate in not having had any "bad arms" develop, and in consequence very little friction is encountered in the work. So far it has not been necessary to prosecute any person for refusing to be vaccinated.

A SUBSTITUTE FOR RUBBER GLOVES IN SURGERY.

To the Editor of the Medical Record.

Sir: In the report of my remarks on the use of a solution of celloidine as a substitute for rubber gloves, which appeared in your valuable journal for October 22, I was incorrectly reported as to the quantity of celloidine and castor oil used in making the solution. The correct prescription is as follows:

℞

Alcohol (96 per cent.).	
Ether	āā ℥xlixss
Celloidine	℥i
M. et ft. sol.; adde Ol. Ricini	℥ss

Frederick Holme Wiggin, M. D.
55 West Thirty-sixth Street, New York.

Malarial Infection.—Guido Baccelli classifies the malarial infections according to periodicity as follows: Quotidian, the chill appearing in the forenoon; tertian, appearing about noon; quartan, in the afternoon. His observations concern especially the pernicious variety common in Italy. Malaria may be pernicious for two reasons, either as a result of the febrile type, or from some condition present in the individual, rendering the results of infection more severe. The latter form of pernicious malaria, he divides into seven main groups: (1) Choleriform or dysenteric, (2) bilious, (3) cardialgic, (4) diaphoretic, (5) syncopal, (6) algid, (7) comatose. There may be also a form in which blood appears in the urine, a very fatal form, in which immediate treatment is essential, and in which the parasite is often not found in the blood. The author regards the appearance of hæmoglobin in the urine as a result of the action of the toxic substances formed in the blood by the parasite. The other pernicious form, resulting from the severe type of fever, he names subcontinuous. It appears suddenly and the paroxysms soon appear so close together that the fever becomes almost continuous. The symptoms are catarrhal, rheumatoid, bilious, or typhoid, or mixed of all these types. The tertian predisposes oftenest to the subcontinuous form. As to the etiology, the author accepts the theory of the parasitic origin of the disease; the clinical course of the fever is determined by the biological cycle of the parasite, the fever rising at the time of sporulation. The symptoms result from poisoning by toxins manufactured in the course of sporulation. The treatment of malaria he considers to be best accomplished by the use of quinine, iron, and arsenic combined.—*Gazzetta Medica di Roma.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, Oct. 27, 1904.

Hæmaturia Due to Bilharzia Hæmatobia, with the Report of a Case.—Richard Frothingham O'Neil states that the parasite, the distoma hæmatobia, is a fluke or trematoid worm with distinct sexes. The parasite is found in almost all parts of Africa. In Egypt it is most common. The exact method of infection of the human species with the disease is not definitely known, as the life and development of distoma outside of the body is entirely unknown. The two most probable avenues of infection are, first, that the embryo is carried into the system by the drinking of infected water or by the eating of shellfish or raw vegetables; and, second, that the infection takes place through the skin or natural openings of the body, this infection occurring during bathing. The genito-urinary system is the one which generally suffers, although the lesions in this disease are not always confined entirely to this part of the body. The adult worm is found most often in the portal system, either in the main vein or some of its tributaries, the most common being those of the urinary apparatus and the rectum. At certain times the worms descend in pairs into the smaller branches of the veins, and the female deposits great numbers of eggs. They finally rupture the vein, escaping into the surrounding tissue, and there form the nuclei for inflammatory changes. When one of these infarcts ruptures into the urinary passages or the rectum a hemorrhage occurs, and gives rise to the hæmaturia so characteristic of the disease, and to the finding of large numbers of the ova in the urine and feces. The urinary bladder is most often affected. The most conspicuous change in the blood is the altered proportion of eosinophiles. The percentage of these corpuscles is very large. The diagnosis is established by finding the ova of the parasite in the urine of feces, or in calculi or masses of tissue which have been removed. The most constant and characteristic symptom is hæmaturia. This is almost always made worse by exercise. As a rule death occurs from anæmia or exhaustion. The disease varies in intensity. The prognosis should be guarded. Treatment is most unsatisfactory, and must be confined to maintaining the general health and treating the symptoms and complications which arise. Salol and methylene blue are recommended. The writer has found the reports of five cases which have occurred in the United States, and to these he adds the report of his own case.

Some Observations on the Occurrence of Broadbent's Sign.—Alice Weld Tallant gives Broadbent's description of this sign, which he observed in cases diagnosed as adherent pericardium, in all of which there was "visible retraction, synchronous with the cardiac systole, of the left back in the region of the eleventh and twelfth ribs; in some of these cases, also, systolic retraction of less degree in the same region of the right back." This sign is often mentioned as one of the most important signs of adherent pericardium. The absence of this sign in undoubted cases of adherent pericardium has, however, been noted. But its occurrence in other conditions has received less attention. The writer, therefore, has examined about 130 cases, and she believes that the results of her observations go to show that retractions in the left back are much more common than is generally supposed, although it is probable that they would be noted more often if they were always looked for during the routine physical examination. Systolic retraction of a marked degree, similar to and often identical with that described by Broadbent, is found in many cases of cardiac hypertrophy in which there is no other reason to suspect pericardial adhesions. Systolic retraction, more often involving the interspaces only, may be seen in the left back in thin individuals, especially if there is marked emaciation. The writer concludes by explaining the probable reason for many of these retractions as follows: Since the pericardium is even under normal conditions, adherent to the central tendon of the diaphragm, it is conceivable that with each systole there is a slight pull on the diaphragm. Under ordinary circumstances this is not marked enough to be transmitted to the points of attachment of the diaphragm to the chest wall, but if the heart is hypertrophied or acting very vigorously, the pull may be sufficient to be visible externally, while in a thin individual even a slight movement would be more easily perceived.

New York Medical Journal, October 29, 1904.

Accessory Thyroid on the Posterior Third of the Tongue.—O. C. Smith reviews the literature of this subject and reports a personal case occurring in a French-Canadian, a man of fifty years, who seven years ago noticed a growth on the back of the tongue. Two years later it was removed and a second removal was done on account of recurrence two years thereafter. About three years later he came under the author's observation, owing to the fact

that the mass had become so large as to interfere with nutrition. An ovid mass was seen on the posterior third of the tongue, obscuring the epiglottis, and rising to nearly the hard palate. It was firm but somewhat elastic, but neither tender nor painful. The external thyroid was normal and there were no enlarged glands. Removal was effected with trivial bleeding, with the écrasem under cocaine anæsthesia.

The Disturbances of Menstruation and their Significance.—E. E. Montgomery discusses amenorrhœa, dysmenorrhœa, menorrhagia and mehorrhagia, and vicarious menstruation. Concerning amennorhœa he notes that ovarian disease (glandula cystoma of both ovaries) sometimes occasions this condition, but its occurrence indicates that the entire ovarian structure has become disorganized. Menstruation may continue regular, however, and pregnancy result even in the presence of this special ovarian condition. Certain ovarian changes not well understood may result in an early menopause. Concerning dysmenorrhœa, the author states that he is very doubtful whether obstruction is ever much of a factor in its production. In cases with a patulous canal the myometrium is often the seat of inflammation, and the painful spasm resembles the occurrence of chordee in the male. Constitutional treatment here is often of more value than local. The so-called ovarian dysmenorrhœa is an inappropriate term, for the reason that the pain is usually felt before the flow with its greatest intensity, and should be considered as an indication of chronic ovarian inflammation. Menorrhagia may end in mehorrhagia. This symptom combination may be the result of constitutional conditions interfering with vascular tension, either locally or generally, as in hepatic, cardiac, or renal disease, causing obstruction in the zymotic fevers, scurvy, and other constitutional conditions. It may be produced by pelvic conditions outside the uterus, as in cystic degeneration of the ovaries, intraligamentary cysts, fibroid growths, ectopic gestation, or periuterine inflammation from uterine involvement, as in threatened abortion, retained fœtal products after labor or abortion, interstitial inflammation of the uterine mucosa, interstitial or submucous myomata, malignant conditions, such as epithelioma of the cervix, adenocarcinoma of the cervix or body, endothelioma, sarcoma, or chorioepithelioma.

Medical News, October 29, 1904.

The Treatment of Scarlet Fever with Antistreptococcus Serum.—Henry L. K. Shaw states that for the last four years all the severe cases of scarlet fever admitted to the Annakinderspital, in Vienna, have received the Moser serum with results not less remarkable than those seen after the use of diphtheria antitoxin. The preparation of this serum is described as follows: An ordinary bouillon culture is made from the heart blood of a fatal case of scarlet fever, and grown for from three to six days. It is then injected subcutaneously into the horse. This produces a slight reaction, with fever, etc. These injections of cultures from different cases are given for more than a week in gradually increasing doses. It takes from seven to nine months to produce a suitable serum, and some horses are never able to produce a satisfactory serum. No carbolic acid is used to preserve this serum. When sufficiently potent the serum, in a dilution of 1 to 250,000, should agglutinate the streptococci. Moser has obtained pure cultures of streptococci from the heart blood of 63 out of 99 fatal cases of scarlet fever, and twice from the cerebrospinal fluid of living children. He has shown recently that streptococci from scarlet fever patients agglutinate in a positive specific manner with the immune serum. Within a few hours the results from the use of the serum are noticed. The fever falls to normal without any signs of collapse or sweating, the pulse rate diminishes, and its quality is improved. The symptoms on the part of the central nervous system subside rapidly, and there is a marked and perceptible improvement in the general condition of the child. All of the symptoms of a general toxæmia quickly disappear. Sequelæ and complications have been less frequent since the use of the serum, and when they do occur they are less severe. No fatal case of nephritis has occurred in any of the injected cases. The mortality for four years before the serum treatment was instituted averaged 14.5 per cent., and for the four years since its employment the mortality has averaged 8 per cent. For the same period in the other scarlet fever hospitals in Vienna the mortality where the serum was not used averaged 13.1 per cent. The only unpleasant result of the use of the serum is the serum exanthem. This is not at all dangerous, although it makes the children uncomfortable. The cases in which a prophylactic dose has been given are still few, but the results are most encouraging. At the present time this serum is prepared only at the Vienna Serum Institute, and is not on the market.

The Etiology of Gastric Hemorrhage.—F. Gregory Connell classifies the different etiological factors of hemorrhage from the stomach as stomachic, extra-stomachic, and unknown. The most frequent cases of gastric hemorrhage is ulcer of the stomach. This is said to occur in about 5 per cent. of the entire population, and hæmatemesis, acute or chronic, is present in from 45 per cent. to 80 per cent. of those afflicted with gastric ulcer. In aggravated cases of acute or chronic gastritis blood may appear in the vomitus, but a distinct hæmatemesis will rarely occur, as it may with tuberculous, typhoid, diphtheritic or other specific ulcerations of the gastric mucous membrane. The hæmatemesis due to carcinoma can generally be differentiated from that caused by ulcer, by means of the history and the character of the vomitus, the "coffee-grounds" vomit of cancer. In the early cases of cancer, and in the unusual cases, it will be impossible to differentiate. Traumatism, direct or indirect, may be the cause of hemorrhage from the stomach. Hæmatemsis following a penetrating wound of the abdomen, does not necessarily imply that the stomach has been perforated. Continuous vomiting or retching, the use of the stomach tube, or aspiration by the stomach pump, may injure the mucosa sufficiently to cause slight bleeding. Operation is another cause of gastric hemorrhage. The chief etiological factor of hæmatemesis, outside of the stomach proper, will be found in various conditions giving rise to interference with the portal circulation. This is best exemplified by cirrhosis of the liver. Any disease of the liver, such as syphilis, senile atrophy, or portal thrombosis, which exerts pressure or otherwise interferes with the portal vein or its subdivisions, may give rise to congestion of the gastric mucosa, and in turn to hæmatemesis. False hæmatemesis is commonly due to the rupture of œsophageal varices or "piles." The blood escapes into the stomach and is then vomited. Just what rôle is played by the central nervous system in exciting gastric hemorrhage, is not definitely known or settled. Gastric hemorrhages have been noted in various nervous diseases. There have been many investigations made to determine the relation between lesions of the nervous system and abnormal conditions of the gastric wall. As to so-called idiopathic hemorrhages, many believe that their origin would be cleared up if more careful examinations were made. Vicarious menstruation and postoperative hæmatemesis are included under the class from unknown causes. Postoperative hæmtemesis has followed a great variety of abdominal operations, and it has also followed extra-abdominal operations. The exact cause of postoperative hæmatemesis is very obscure, and the subject will have to be carefully investigated before an accurate understanding will be reached.

American Medicine, October 29, 1904.

Angina Pectoris.—John Knott gives a most interesting résumé of the literature on this subject. This disease or group of symptoms is English above all things, one of luxurious living and full feeding rather than of the contrary conditions. It occurs preferably in subjects with a tendency to fatty deposition. As to the internal conditions which determine the external expression of these symptoms known as angina pectoris, the writer thinks that the most important evidence of any has been furnished by Lancereaux and Peter, who in several cases have reported the existence of distinct evidence of neuritis in the nerves of the cardiac plexus. This would account for the pain and the irritative reflex inhibition, which would be a very possible consequence of the involvement of the branches of the pneumogastric nerve involved in that plexus, and would offer an efficient cause of the sudden death which so often marks the period of this painful affection. The writer points out a considerable similarity between the paroxysms of angina and the painful cramps of alcohol neuritis. He thinks that the variable amount of radiation of pain may be due simply to the varying extent to which this neuritis has extended to other filaments of the vasomotor nerves. He asks if this vasomotor neuritis may not be more intimately associated with the distribution of atheroma than pathology has yet pointed out. This affection occurs far more often in males than in females. It is most common after the fiftieth year of life. As has been noted, the majority of these patients belong to the Anglo-Saxon race. The "intellectual and anxious" are specially prone to its invasions. The temper of the sufferer is often a rather characteristic feature of the origin and progress of angina. As to the treatment of this affection, the writer states that the application of amyl nitrite to the relief of the paroxysms of angina pectoris is a boon which has been conferred upon suffering humanity by Sir Lauder Brunton, an achievement which by itself is worthy of winning for him the high reputation which he enjoys. The writer has personally been disappointed in the results of the employment of nitroglycerine.

Is Not the Treatment of Congenital Clubfoot Begun Too Early?—V. P. Gibney first calls attention to the general trend of the modern teaching on this point. The physician is almost invariably advised to begin the treat-

ment of clubfoot at birth, or at least soon after. The deformity begins at an early period of fœtal life, and the presumption is that it steadily increases up to birth. The writer from his large experience with these cases questions, to say the least, the beginning of vigorous treatment immediately after birth. He puts in a strong plea for infant feeding and hygiene, and inclines rather to the postponement of the treatment of clubfoot until after those important items have been attended to. The excoriations and the strained tendons and ligaments must inhibit digestion, and if digestion is inhibited, nutrition cannot proceed satisfactorily. During the last year or two, the writer has declined to treat cases of congenital clubfoot in young infants, and has advised the parents to wait till the baby is old enough to walk. The writer's contention has been along the lines of mitigating the severe forms of treatment. It should not be inferred from the above that nothing whatever is to be done in the way of correcting the deformity during the first eighteen months. A certain number of cases of clubfoot of moderately high degree are corrected fully 80 per cent. or 90 per cent. by the mother's hand alone. Such cases should be seen from time to time, and this work should be supplemented by simpler forms of apparatus. The mother can be taught to apply a side-splint with a soft roller bandage reinforced by a strip of rubber adhesive plaster. This may be removed as often as she has time for manipulating the foot. There are a large number of cases, however, that are not successfully managed by the maternal hand. One reason may he that the mother is often told that she can do little or nothing for the child. Some babies are fully able to stand moderately vigorous treatment without any interruption of digestion. But these are rather the exception. The writer calls attention to the fact that doubtless the facets of the tarsal bones can be modeled after the second summer, especially by means of the use of the foot. This would be analogous to the deepening of the acetabulum, by the use of the head of the femur if this bone is in proper position. The writer emphasizes throughout the paper the importance of regarding the feeding and the hygiene of the child as supreme.

Indicanuria Complicating Typhoid Fever.—Judson Daland believes that indicanuria should be viewed as a complication of typhoid fever which should be removed. Indicanuria often exists without symptoms, but this fact should not be accepted as signifying that no injury is being experienced by the patient. The writer employs the following test for indican: To 10 cc. of filtered urine add one drop of a 1 per cent. solution of potassium chlorate, then 5 cc. of chloroform, and lastly 10 cc. of pure hydrochloric acid of a specific gravity of 1.19. This is thoroughly mixed by pouring it from one test tube to another. The indigo which is set free is dissolved in the chloroform. The maximum coloration is secured in ten minutes. The writer has found indican present in a large proportion of cases of typhoid urine. If it is found, he orders the mouth to be examined and cleansed both before and after the patient takes food. Suppuration of the nasal chambers of the sinuses communicating therewith, and retained decomposing material concealed within the crypts of the tonsils, demand local treatment. Food, especially milk, in passing through an unclean oropharynx quickly undergoes fermentation and putrefaction. Cleanliness of the mouth, pharynx and nares is most important. Calomel, a twelfth of a grain, thoroughly triturated with a grain of sugar of milk, may be taken dry on the tongue every second hour till a grain has been taken. This will stimulate the secretions. The calomel is followed by a drachm of sodium phosphate dissolved in freshly boiled water, taken early in the morning. No food is given for an hour. The juice of half a lemon may be added, if there is no contra-indication. If indicanuria persists, a gentle irrigation of the colon with one or two quarts of a warm normal salt solution may be given. The soft rubber colon tube is introduced for a distance of eight inches, so that the outlet shall be above the sigmoid flexure. The diet is at first exclusively animal broth. Peptonized milk should gradually replace the broths after the gastrointestinal canal has been thoroughly cleared of its contents. Milk and broth should not be consumed at the same time. As soon as possible, an ordinary patient should consume each day from one to two quarts of peptonized milk at two-hour intervals, and at twelve hour intervals a good strong animal broth. Pure water or imported vichy is often of value as a vehicle by which the toxic substances may escape from the body. Ordinarily the treatment of indicanuria is restricted to that period when the ulceration of the intestines is least active. If indicanuria is present during the third week, or at any time when it is believed that the ulcerations are active, unless the toxic symptoms are serious, the treatment for indicanuria should be omitted.

Journal of the American Medical Association, Oct. 29, 1904.

A Chief Predisposing Cause of Appendicitis.—G. Rubin notes the fact that the majority of cases of appendicitis occur between the ages of ten and thirty (about three-fourths, he states), and also the fact that constipation favors, according to many authors, the development of the disease. According to the author of this paper, the disease is directly referable to the following sequence of intestinal conditions: the accumulation of gases below the ileocecal valve and their voluntary retention; the ensuing distension of the cecum and dilatation in various degrees of the cecoappendicular orifice; the entrance into the appendix of larger fecal masses than are readily expelled; the interference with the vascular circulation and resulting erosion of the mucosa of the appendix with subsequent infection. Portions of intestines, about fifty cm. in length, including cecum and appendix, were removed from cadavers, and after the colonic end was ligated small shot, peas, and beans were introduced through the open end, and the bowel manipulated so as to imitate peristalsis. None of the small bodies entered the appendiceal cavity, although the appendix was held at the most pendant point. Then the bowel, still containing those substances, was inflated, the same process of rolling repeated, with the result that in all the experiments, with one exception (where only one shall shot entered owing to an hypertrophied appendical wall and a constricted lumen) the appendix was filled with shot, and in two cases peas of medium size also gained entrance. Ten such experiments were carried out. It may be added here that the appendix was readily ballooned during the process of inflation. It is reasonable to suppose that similar phenomena might occur in the living.

Intubation.—B. R. Shurly reports a series of unusual cases, and in summarizing his views states that obstruction of the tube is more common after large doses of antitoxin. Therefore the string should be left in when indicated. Ordinarily, the tube should be removed at the end of the fourth day. Large doses of antitoxin conduce to conditions favoring early tube removal. Intubation is usually indicated as the primary operation in papillomata of children and acute stenosis of adults.

The Lancet, October 22, 1904.

The Treatment of Lupus Vulgaris During the Last Twenty-five Years.—This question is reviewed by Malcolm Morris, who has treated over one thousand cases of the disease by various methods. His experience leads him to summarize as follows: (1) It must be confessed that after every kind of treatment, whether used alone or in combination with others, recurrence is still very common. (2) As a general statement it may be laid down that small superficial quiescent patches are curable. (3) When the disease is of moderate extent and situated on the face Finsen's method, either alone or combined with the application of the *x*-rays, and supplemented by the use of caustics, is the most efficient mehod in regard to cosmetic effect and probably also in regard to permanency of result. The treatment, however, requires so much time that it is practically incompatible with the pursuit of any avocation needing close personal attention, and directly or indirectly it entails considerable expense. (4) If a rapid effect is desired reliance must still be placed on gentle cautery if the disease is on the face, and excision if it is on the limbs or the trunk, supplemented in the former case by pyrogallol, salicylic acid, nitrate of silver, or other caustics. (5) very extensive and severe cases in which the health is affected must be dealt with by the general measures (open-air treatment, feeding, exercise, etc.) used at the present day in the treatment of pulmonary tuberculosis.

Drainage of the Pericardium.—Two cases are reported by H. S. Pendlebury. One survived and made a good recovery, while the other died. The author prefers a vertical incision to one along the lower border of the seventh rib, because (1) it gives access to the sac without interfering unduly with the attachments of the rectus muscle, and (2) because it permits the operator to proceed at once with the removal of the sixth costal cartilage if this becomes necessary. About twenty minutes are required for the operation. In simple effusion the drainage tube may be removed in three or four days. The presence of the tube does not seem to embarrass cardiac action. The removal of the seventh costal cartilage is advised except in cases of very young children. The internal mammary and superior epigastric vessels are pushed towards the middle line or divided and the cellular interval—"costo-xiphoid space"—between the seventh costal cartilage, ensiform cartilage, and the attachment of the diaphragm is broken into. The triangularis sterni, with the intercostal membrane and muscle, is divided in the line of the incision up to the sixth costal cartilage, then carefully pushing aside both the right and the left pleura the operator, in order to avoid all danger of opening the peritoneal cavity, should incise the pericardium just above the level of the base of the ensiform cartilage and with his finger enlarge this incision downwards into the costo-xiphoid space.

British Medical Journal, October 22, 1904.

Intrauterine Infection of the Fœtus in Smallpox.—Thomas Percival records another instance of this kind. On January 28, 1893, a woman came from a house in which there had been smallpox to the writer's district. She was confined on February 6 and developed smallpox two days later. The baby was vaccinated, showed smallpox on February 16, and died on February 20.

A Cervical Tumor.—J. Wishart Kerr reports this case: The patient, aged 18, had a growth which had increased in size since she was a little girl. The whole right side of the face had hypertrophied in order to carry the weight of the tumor. The tumor bulged into the mouth, the floor of which was completely gone. Eating was becoming impossible and speech was reduced to inarticulate grunts. Six unsuccessful attempts had already been made to remove the tumor. On account of the condition of the parts, a preliminary tracheotomy was impossible. Chloroform was administered and an incision was made in the middle line of the neck, from the chin down to within two inches of the base of the tumor. The incision was then extended outwards and upwards to the left. The blood vessels were secured and the platysma and cervical fascia were opened up. The tumor was held away from the windpipe. An incision was then made across the right side of the neck as far as the angle of the jaw and the flaps turned up and down. The tumor, which was a lipoma, was shelled out fairly easily. But its firm attachment to the root of the tongue had to be carefully dissected out. It was found that the tumor had been lying over the trachea, and close on to the spinal column; it also extended up behind the pharynx to the base of the skull. An appalling gap was left. A floor for the mouth was made out of the cervical fascia, the incisions stitched up, and a drainage tube inserted. The blood supply to the tumor was large, and the veins had grown enormously. For three days the patient was fed per rectum. Then a tube was passed along the mouth to the back of the throat, and feeding took place through it. The patient soon fed herself from a feeding cup. The later history was uneventful. The tumor weighed nearly four pounds, and was a typical fatty tumor.

Operation for Cancer of the Womb in Germany.—Olshausen discusses the operative treatment of carcinoma uteri, as to which is the preferable method, the employment of the abdominal or the vaginal route. In operating upon cancer in general, the writer believes that the chances for radical cure are much greater if the operation extends widely beyond the disease, and if the local lymphatic glands and connective tissue are removed. But he adds that it is a question in his mind how far this can be done in cases of cancer of the uterus, and whether the result can promise much compensation for the increased risk of this method. It is impossible in the operation to see which glands are affected, or if they are affected at all. Commonly the glands do not become affected in carcinoma uteri till very late in the course of the disease, but, nevertheless, in some cases they become affected very early. Small glands may contain cancer cells, large ones may be normal. Such a dissection as that performed in the axilla in the modern operation for mammary cancer is absolutely impossible in the pelvis on account of the anatomical relations. Thus the abdominal operation will never promise a radical cure if the cancer has progressed beyond the uterine tissue. As to the primary mortality, only one operator in Germany has had satisfactory primary results. As a factor of the high mortality, injuries to the adjacent organs must be considered, especially to the urinary tract. As soon as the cancer is no longer confined to the uterus itself, the chances of a radical cure are improbable by any method of operating. If the cancer is still confined to the uterine tissue the vaginal operation is certainly sufficient. The writer states that great progress has been made with the vaginal method. From 1903 until the present date he reports 137 cases, with 6 deaths, or 4.4 per cent. He does not state that the abdominal operation is to be entirely excluded. He performs it in those cases in which he fears that the cancer has spread and surrounded the ureters. The ureter is more easily accessible by the abdominal than by the vaginal route. The writer does not advise clearing out the glands, for when they are once affected the cases must progress and end fatally, perhaps, with very few exceptions, whether operated upon or not. He concludes by saying that it has by no means yet been shown that a greater number of cases have been radically cured by the abdominal operation than by the vaginal method. The choice of the vaginal operation is therefore justified up to the present time, and possibly will remain so for the future.

Berliner klinische Wochenschrift, October 10, 1904

New Color Reactions for the Sugars.—Neumann describes a modified orcin test by which pentose and hexose may be detected and various members of these groups differentiated. The technique is as follows: Ten drops of the watery solution to be tested are mixed with 5 cc. of glacial acetic acid and a few drops of a 5-per cent. alcoholic orcin solution and heated to boiling. The test tube is placed in a holder and concentrated sulphuric acid is added drop by drop. Constant shaking is necessary to keep the fluid from spurting out of the tube. The acid is added till a decided color is reached. The amount required varies with the concentration of the solution tested, it is useless to add more than fifty drops as an excess of acid decomposes the orcin and gives a yellow color. No more acid should be added after a distinct color is obtained, or misleading mixtures of colors will result. The color is judged and the spectroscopic examination of the fluid made when it has cooled. If too deep, the fluid may be diluted with acetic acid without changing the color. Arabinose gives a violet red; xylose, warm, violet blue; cold, blue; glycuronic acid, warm, green; cold, greenish blue; glycose, brownish red; fructose, warm, brown; cold, yellow brown.

Glycuronic Acid Formation in Man.—Wohlgemuth publishes the results of a series of analyses made of the urine in a case of cocaine poisoning, which tend to corroborate the views of those who believe that glycuronic acid is formed as a result of insufficient power of the organism to oxidize sugar. In this case large quantities of phenol-glycuronic acid were excreted, because, as a result of the cocaine intoxication, the powers of oxidation were diminished, and the body was unable to oxidize the sugar, which it normally would have burned, as well as the glycuronic acid formed in response to the presence of the cocaine and camphor given as a stimulant. A part of the sugar and a part of the glycuronic acid thus reached the urine unchanged. This inability decreased from day to day, as was shown by the gradual diminution in the amount of sugar. The glycuronic acid seized upon the phenol, which normally enters into other compounds, and combined with it, as it possesses a great affinity for this, and was excreted as phenol-glycuronic acid. The case is interesting as throwing light on the obscure question of the origin of glycuronic acid.

Pus Studies.—Posner has made morphological studies of the pus cells obtained from gonorrhœal cases. He differs from some writers, who believe that vacuolization of the protoplasm of the cells indicates a late stage of the disease, since he has found it well marked on the second to seventh day, and has often been unable to detect it in older cases. He regards pycnotic nuclei as representing degeneration, but does not draw any diagnostic conclusions from this fact. In four cases of nongonorrhœal urethritis he found this type of nucleus three times, and therefore questions whether it may not be the result of the presence of bacteria other than the gonococcus. Eosinophiles do not appear to have the connection with the prostate that some authors claim for them. They are most abundant from the fourth to the sixth week, are rare in the early and later stages of the disease and in nongonorrhœal urethritis. The author believes that the presence of many eosinophiles indicates a true gonorrhœa in about its fourth to sixth week. Mononuclear cells are not especially significant of late stages of the disease, as Pappenheim has claimed. Epithelial cells indicate a regenerative process, and therefore point to beginning cure.

Münchener medizinische Wochenschrift, Oct. 11, 1904.

The Treatment of Hernia by Alcohol Injections.—Brodnitz calls attention to this method of treating hernia, which was advocated by Schwalbe in 1870, and then allowed to fall into disuse again. The author has tried the plan on seventy-three patients, of whom twenty-five were children. Of the cases with large ruptures, the ring admitting one to two fingers, six months after termination of the treatment four out of nineteen had recurrences. In twenty-six other cases there has been no return of the hernia. In children the author injects 0. 5-1. g of absolute alcohol every two to three days, depending on the intensity of the reaction, into the tissues of the inguinal canal. Adults receive from 3-5 g. at each sitting. The treatment is rather painful, and it is well to precede it with a preliminary cocaine injection. The local reaction produced is variable. After the first two to three injections but little disturbance is noted; after that swelling appears at the site of the injection. This point is avoided in subsequent treatments, and after eight to ten injections a uniform swelling and thickening of the inguinal canal results, which prevents the entry of the finger into it or the egress of the intestine. The author says the method is suitable for children, for persons with incipient hernia requiring the use of a truss, in cases where the hernia cannot be retained by a truss and operation is contraindicated for some reason, and for patients who dread operations and prefer the uncertainty of this method to the more reliable surgical procedure.

Spinal Anæsthesia in Obstetrics.—Martin gives the details of thirty cases in which spinal cocainization was performed during labor. In each case 1.0 cm. of a 1-2,000 adrenalin solution was first injected, followed in about five minutes by the cocaine injection. Anæsthesia was obtained in all cases except one, and in this sensation was diminished. Marked variations existed as to the duration of the anæsthesia. In nine cases it did not exceed half an hour, in other instances it lasted from one to three hours, and in two cases it persisted for four hours. The third stage was not modified in any undesirable manner, and sutre of the perineum was performed painlessly in several instances. Marked nausea and vomiting were frequently caused, as well as sensations of general malaise, and these symptoms were not controlled by subcutaneous injections of caffeine salicylate, as Tuffier has recommended. The degree to which the pains were modified was variable, but in cases in which the delivery took place within one to one and a half hours the effect was very good. The uterine contractions were somewhat retarded and the abdominal muscles were called into play only when the patient was urged to do so. The puerperium and milk secretion were not influenced by the spinal anæsthesia. The author considers these results so favorable that he intends to make further tests of the method in cases where the use of chloroform is undesirable, in order to determine in what respects spinal anæsthesia is to be preferred to the ordinary methods.

Hemorrhage from the Visceral Wound in Gastroenterostomy.—Doberauer says that the subject of bleeding from the cut edges of stomach or intestine in operations on these organs has received very little attention from writers. It is usually stated that the customary sutures will control all hemorrhage as soon as they are placed, and that it is unnecessary to stop to ligate any small vessels in the cut tissues. That mishaps may, however, happen is shown by a case of the author's, in which, after a gastroenterostomy, the patient gradually became weaker, vomited fresh blood and went into collapse. It finally became evident that the abdomen must be reopened, and this was done. The upper part of the intestine was found filled with blood, which came from an arterial and a venous vessel in the intestinal wall. These were ligated and the operation completed as before, and though the patient had been so stuporous as to require no anæsthetic, she promptly recuperated and made a good recovery. This incident does not, in the author's opinion, require that our technique should be modified, and every bleeding vessel be separately ligated in such operations, but it does indicate the necessity for a very careful laying of the sutures and taut adjustment of them. Whether the use of clamps to prevent the escape of intestinal contents during the operation favors the occurrence of secondary hemorrhage or not is difficult to decide; such appliances probably have little to do with the matter. Several instances of post-operative bleeding of this sort described by other authors are quoted.

Deutsche medizinische Wochenschrift, October 13, 1904.

The Therapeutic Effect of Radium Rays.—Werner and Hirschel treated by means of radium twenty-two patients, including five cases of carcinoma, one of melanosarcoma, five of angioma, seven of lupus, two of nævus, one cheloid and one tubercular ulcer of the tongue. The six cases of malignant disease did not yield favorable results, and the authors do not feel encouraged to persevere in this direction. The treatment of operable growths by radium is not to be recommended, and on the other hand, the chances of cure are so slight in inoperable cases that the predictions first uttered for this treatment do not seem likely to be fulfilled. With the benign growths more satisfactory results were obtained. The authors are of the opinion that in cases where the treatment must be forced, it is preferable to make frequent and long-continued exposure to the radium, for though the resulting necrosis of the skin produces ulcers requiring weeks to heal, yet the treatment of these is simple, and the scars remaining are not disfiguring. It is open to question whether mild applications are not more injurious than helpful, owing to the stimulation they cause, and the authors conclude that the radium should be applied with vigor or not at all.

Motility of the Stomach in Achylia.—Elsner says that the prevailing idea that in chronic gastritis or achylia the motility of the stomach is unimpaired or even increased rests mainly on the observation that attempts at removing the gastric contents after a test meal in such patients usually do not produce a sufficient amount of residue. If the stomach is washed out, however, after such an unsuccessful attempt, it will be found that a considerable amount of material is obtained. This is explained by the fact that through the impairment of gastric secretion the bread comprising the test meal is insufficiently moistened and forms a solid mass, which does not readily enter into the stomach tube. The failure to get a satisfactory amount of residue in these cases is therefore due to the thicker consistency of the gastric contents, and not necessarily to a change in the motility. The author describes a roughly approximate test of motility, which consists in giving the test meal after it has been subjected to a preliminary softening, and then washing out the stomach one hour later. The material obtained is decanted into graduated cylinders and the amount of sediment read off at the end of twenty-four hours. If large lumps appear in the washings, these should be broken up before sedimentation. From results obtained in this way the author concludes that achylia does not have a constant effect on gastric motility, and that no fixed statement can be formulated for this feature of the disease.

French and Italian Journals.

Dissimulation in Reference to Some Cases of Insanity.—E. Crisafulli tells us that dissimulation in some cases of insanity becomes of the greatest interest medico-legally, as well as from a medical point of view. An insane person may have all sorts of ideas injurious to himself or to others, and may yet conceal them so effectually that for years the public and his friends do not realize that he has any mental trouble, until some overt and perhaps harmful act causes his case to be inquired into more carefully. The demeanor of such persons is very various; the deceitful acts may come in episodes, or the dissimulation may be persistent and be one of the causes of the mental trouble. The patient may feign a state of mind that is exactly opposite to the real one, in order to conceal his real feelings. After entering an asylum he will plan to seem for a long time sane, in order to obtain his liberty, and on going home will relapse into the old condition. Insanity may be recognized only when a will is read, which imposes ridiculous and harmful conditions upon the heirs. The patient may conceal ideas of suicide or homicide, while exercising great cunning in obtaining the weapons needed to commit some terrible act. This feigning only goes on for a time, and in the end the power to conceal the mental failure breaks down, and the real state of things appears. The author mentions instructive illustrative cases, and concludes by saying that the form of the malady, the physique of the patient, and his surroundings, influence the manner of his deceits, and the length of time that he can appear sane. The feigning usually increases the psycopathy, brings about exacerbations of disease, and forms one of the factors that aid the disintegration of the diseased mind. The sick man usually realizes that his mind is in an abnormal condition, but even in cases when he does not do so he may still make attempts to deceive.—*Gazzetta Medica Lombarda*, September 26, 1904.

A Case of Primary Cancer of the Vertebral Column.—M. Péhu and J. Coste state that, although it is relatively common to find secondary foci in the vertebral column, in the course of the various visceral neoplasms, it is not the same with primary cancer of this region. The indisputable cases of this kind are rare. They report a case of a patient who was suddenly attacked with a complete paraplegia. At the autopsy the writers discovered the existence of a primary cancer of the vertebræ. The man was 54 years old, with a good family and personal history. He was brought to the hospital on account of pain which had first appeared in his legs, but which shifted to the region of his waist. He had lost weight and had a cachectic aspect. Palpation of the abdomen was almost impossible on account of the pain. There was the same difficulty with the lumbar region, although there was nothing abnormal to be noticed on inspection. Mobility, the sense of feeling, and the reflexes, were all normal. Nothing abnormal could be detected in any of the organs. The urine was clear, but had a little albumin in it. One morning the patient was up for a short time, and at the moment when he lay down again he had a sharp pain in the lumbar region, and immediately there developed complete paralysis of the lower members. The reflexes had completely disappeared. There was retention of urine, but this condition gave place several hours later to incontinence. Eschars developed. The patient slept constantly, although he would waken when spoken to, and would answer questions. Four days after the appearance of the paralysis he died. At autopsy the viscera were found to be normal, but a tumor was discovered which had originated in the eighth and ninth dorsal vertebræ. The tumor had destroyed these vertebræ to the extent of causing a subluxation at this point. Histological examination showed that this tumor had its origin in bony tissue. The spinal cord at the point of fracture of the vertebral bodies, which had been caused by the inroad of the growth, looked as if it had been cut by a sharp instrument. There was complete myelomalacia. Surgical intervention under the existing conditions would have been of no avail.—*Lyon Médical*, October 9, 1904.

Book Reviews.

First Lessons in Food and Diet. By Ellen H. Richards. Instructor in Sanitary Chemistry in the Massachusetts Institute of Technology. Boston: Whitcomb & Barrows. 1904.

The text of this little book is presented in ten chapters or lessons. It is intended for use in schools and by women's clubs. The author discusses such topics as Plant Life, Food for the Child, the School Luncheon, What Shall We Eat as a Family? Daily Food, and Principles on which Bills of Fare Are Made.

The Medical Epitome Series. Nervous and Mental Diseases. By Joseph Darwin Nagel, M.D. 266 pages. Philadelphia and New York: Lea Brothers & Company, 1904.

Essentially a book for "crammers," clear and yet not graphic. In a science in which so many opposing theories are held as in neurology, it is hardly possible to weave the writings of the great teachers into a "compact fabric," as the editor claims to have done. He neither takes the responsibility for the statements made, nor does he cite his authorities.

Serums, Vaccines, and Toxines in Treatment and Diagnosis. By William Cecil Bosanquet, M.A., M.D., Oxon., F.R.C.P., Lond., Physician to Out-Patients, Victoria Hospital for Children, etc. Chicago: W. T. Keener & Co.; London: Cassell & Company, Limited, 1904.

This attractive little volume is intended to serve as an introduction to the broad field which is now covered by the title. So much experimental work is being done at present in this department that the mass of accumulated material is too great for any one not especially interested to keep pace with and the author provides a short cut for those who would gain a bird's-eye view of the subject without studying at length the voluminous literature. The various topics are treated simply, yet with sufficient fulness for the purpose, and we can commend the book to those interested.

The Physiological Feeding of Infants. By Eric Pritchard, A.M., M.D., M.R.C.P. Second Edition. Chicago: W. T. Keener & Company, 1904.

This book is so rewritten and amplified as properly to be considered a new book. It is written in a style so clear and simple that a nurse of average intelligence will have no difficulty in understanding it; and so convincing, that a general practitioner will gladly abide by its teachings. The book has two distinct parts. The first treats of the actual feeding of infants, laying stress on the adaptation of food to individual needs; on breast feeding when possible; on milk modified according to percentage composition of human milk, as second choice; and on the use of gravity cream. Tables are given for modification of milk, and recipes for substitute foods. The second part considers the characteristics and development of a normal infant, with the causes and first indications of a departure from the normal.

The Suppression of Tuberculosis. By Prof. E. von Behring. University of Marburg; authorized translation by Charles Bolduan, M.D. New York: John Wiley & Sons, 1904.

Monographs on the tuberculosis question follow one another with such rapidity that it is difficult to keep track of them all. The present pages dwell particularly on phthisiogenesis in man and animals, and furnish suggestions concerning the hygiene of cow stables and the production of milk for infant feeding. The author believes that milk fed to infants is the chief cause of tuberculosis, hence the lines along which he elaborates his thought. He believes it probable that in thickly populated countries, practically every person is at some time or other infected with tuberculosis, the outcome of such infection depending in a high degree on the physical state of the individual and the accidental conditions of the infection. The book is suggestive alike to the physician, sanitary officer, and veterinarian.

The Doctor's Red Lamp. A Book of Short Stories Concerning the Doctor's Daily Life. Selected by Charles Wells Moulton. Chicago, Akron, O., New York: The Saalfield Publishing Co., 1904.

This is the second volume of the "Doctor's Recreation Series," the first of which was noticed in this column a few weeks ago. It is a well-arranged selection of stories from various sources, in each of which a medical man is one of the leading characters. Some of the stories are familiar to readers of current literature, others are not, but all are interesting and well told, and physicians, even those who occasionally tire of the shop and prefer to rest their brains in outside reading, will be glad to have the stories conveniently grouped in a volume by themselves. Among the authors of the various tales are Conan Doyle, Ian Maclaren, Ruth McEnery Stuart, Mrs. Oliphant, and Henry Seton Merriman. There are twenty-two stories and four full-page pictures. The book is well printed and prettily bound and is in every way an addition to the physician's library.

A Text-Book of Physiological Chemistry for Students of Medicine and Physicians. By Charles E. Simon, M.D., of Baltimore, Md. Second edition, revised and enlarged. Philadelphia and New York: Lea Brothers and Company, 1904.

The second edition of Simon's now well-known manual of physiological chemistry presents the same matter as the first, which was reviewed in these columns, and, in addition, has received the benefit of a thorough revision, and of the insertion of accounts of the latest researches in this field. The progress of investigation made necessary an almost complete re-writing of the chapters on albumin, on nitrogenous metabolism, and on the digestive ferments. In its present shape, therefore, the book offers a résumé of the most modern researches on its subject, together with a thorough treatment of the fundamentals of physiological chemistry. A valuable addition, also, is a scheme for a series of laboratory exercises on the various topics discussed. The book will undoubtedly appeal to students and to the physician who has time and inclination to refresh his knowledge of the science which is the basis of so much of our present and future knowledge of disease and its treatment.

Friedberger and Fröhner's Veterinary Pathology. Authorized Translation. Translated and Edited by M. H. Hayes, F.R.C.V.S., author of "Points of the Horse," "Veterinary Notes for Horse Owners," etc. With notes on Bacteriology by Dr. G. Newman, D.P.H. Volume I. London; Hurst and Blackett, Ltd.; Chicago: W. T. Keener & Co., 1904.

Friedberger and Fröhner's *Lehrbuch der speciellen Pathologie und Therapie der Hausthiere* is a recognized authority on veterinary medicine, and it is used as a text-book in the veterinary colleges of both Germany and France. "Owing to the fact that the infective diseases of animals can in many cases be communicated to man, and that their occurrence in our meat and milk producers is a serious question of public hygiene, the first volume of this translation will appeal to doctors as well as to veterinary surgeons." By far the greater part of this volume deals with the infective diseases, and we may mention, as of particular interest, the section on tuberculosis. The editor has provided articles on Surra, South African Horse Sickness, Australian Tick Fever, Ixodic Anæmia in Jamaica, and Louping Ill, subjects omitted in the original. Dr. Newman's Notes on Bacteriology are a model of their kind. The book is both interesting and instructive.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By James Nevins Hyde, A.M., M.D., Professor of Skin, Genito-Urinary, and Venereal Diseases, Rush Medical College, Chicago; Dermatologist to the Presbyterian, Augustana, and Michael Reese Hospitals of Chicago, and Consulting Dermatologist to the Chicago Hospital for Women and Children, and Frank Hugh Montgomery, M.D., Associate Professor of Skin, Genito-Urinary, and Venereal Diseases, Rush Medical College, Chicago; Professor of Skin and Venereal Diseases, Chicago Clinical School; Attending Physician for Skin and Venereal Diseases, St. Elizabeth Hospital, Chicago. Seventh and Revised Edition. Philadelphia and New York: Lea Brothers & Co., 1904.

The latest edition of this excellent work has been thoroughly revised. Much of the older material has been eliminated, while the results of modern researches are incorporated in this present volume. The engravings and plates, as well as the text, have been revised. No effort has been spared by the authors to present a treatise on Dermatology that represents the science in its most advanced state. The new subjects treated are: General Pathology of the Skin, Radiotherapy and Phototherapy, Granulosis Rubra Nasi, Pyroplasmosis Hominis, Erythema Elevatum Diutinum, Ulcerating Granuloma of the Pudenda, the Psoriasiform Dermatoses (Parapsoriasis), Acrodermatitis Perstans, Dermatitis Vegetans, and Acrodermatitis Chronica Atrophicans. Various sections have been largely or wholly rewritten, among which are those dealing with Psoriasis, Dermatitis exfoliativa, Pityriasis rubra, Pityriasis rubra pilaris, Lichen ruber, Lichen planus, Ichthyosis, Elephantiasis, Acromegaly, Xeroderma pigmentosum, Cutaneous tuberculosis, Erythema induratum, the Dermatoses associated with tuberculosis, Blastomycosis, Acrodynia, Pellagra, Oriental sore, Phagedena tropica, Piedra, and Verruga peruana. The technique of both the Finsen light and the *x*-rays and their value in skin diseases have been fully considered, both separately and in connection with those affections in which they have proved useful. The bibliographical references are most conveniently arranged, and are of great value. As in former editions, both the apothecaries and the metric systems of weights and measures are used in the discussion of remedies.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 20, 1904.

Dr. Andrew H. Smith in the Chair.

Primary Malignant Neoplasms of Lung and Pleura.—Dr. Isaac Adler delivered this, the Wesley M. Carpenter Lecture for 1904. The disease in question was one of the rarest, and most text-books devoted but very little to its consideration. The literature was very widely scattered. The treatment of malignant neoplasms of the lung and pleura was almost entirely neglected, the majority of the writers devoting themselves to pathology and the minute anatomy of the condition. Little was said about sarcoma of the lung and pleura. The lung and pleura were so close and interdependent that it was very difficult at death to state which gave rise to the primary trouble. Personally the speaker had had experience with ten cases, all of which had given him an opportunity to study them closely for a long time, and, in the majority of these cases, the correct diagnosis made during life was confirmed at autopsy. He thought that a general survey of the whole subject might be of some use and interest.

In all, 330 cases were collected from the literature. The earlier reports presented difficulties in obtaining proper data. All doubtful cases were excluded from their consideration, and only such cases were accepted in which the autopsy records confirmed the diagnosis. In the majority of cases the original publications were studied. Primary malignant neoplasms of the lung and pleura seemed to be considered very rare, although this might be due to many cases not being diagnosed. Statistical material was very insufficient. Wolff of Munich, in 20,160 autopsies, found forty-five instances of primary cancer of the lungs. Figures were given to show that the percentage of cases seemed to increase within recent years, in all probability because the cases were more frequently diagnosed. He showed a specimen of adenocarcinoma which involved the middle lobe of the right lung near its root, which might have passed for a pneumonic or other consolidation, and which was only found by accident in a woman who had died of post-operative sepsis. The probabilities were that primary malignant disease of the lungs and pleura was much more frequent than generally supposed. Notwithstanding this, malignant tumors might be said to be rare in this situation and it was a curious fact that those organs which were the most often affected by secondary deposits, rarely were the seats of primary ones. The proportion of males and females was about five to one. In one collection of cases there were 227 males and 90 females. The right side was more often involved than the left, one reason being, perhaps, that the right bronchcus was more perpendicular. In the series of cases reported, the right side was involved in 155 cases, the left in 142, the remainder being doubtful. There was one case under one year. The history of this interesting case was reviewed, and there was no question but that it was a primary carcinoma. In the first decade there were two cases; in the second decade there were eight cases; in the third decade there were twenty-seven cases; in the fourth decade there were thirty-six cases; in the fifth, sixty-three cases; in the sixth, eighty-four cases; in the seventh, seventy cases; in the eighth, twenty-two cases; after the age of eighty years there were but two cases:

Dr. Adler considered the pathology of carcinoma, sarcoma, and epithelioma of the lung and pleura. Carcinoma was by far the most common; in his ten cases all were of this variety except two or three. He had found it extremely difficult accurately to classify these growths from the literature. Undoubtedly carcinoma was met with in 211 cases and sarcoma in twenty-two cases; endothelioma was noted in twenty-four cases, ten were mixed cases, and the remainder he failed to classify. After referring to four types of carcinoma, he said that the great majority of these cases originated from the bronchi. Cancer of the lung had a tendency toward ulceration, the bronchi breaking down with the formation of cavities. The dissemination of cancerous material was by way of the lymphatics, although it was found to be carried by the blood vessels as well. Bronchial cancers at the root of the lungs formed very large tumors in the mediastinal spaces; adhesions here readily formed, involving the pericardium and other nearby structures. Cancerous thrombi formed which proliferated. There were many complications to the clinical picture of cancer here, especially the tendency to hemorrhage. The aorta itself had never been known to be involved by a tumor. The microscopical picture of carcinoma of the lung was very complicated because of complexity of structure. The diagnosis between carcinoma and sarcoma was often found to be extremely difficult. The essential feature in the former was the character and behavior of the epithelial cells. The histogenesis of this class of tumors was very unsettled, and in the majority of the cases of primary carcinoma of the lungs was very obscure and doubtful. Sarcomata of the lungs had not received much attention in pathology. They occurred as massive tumors, and softening and degeneration, with the formation of cavities, rarely occurred. Lymphosarcomas had no tendency towards degeneration at all. Little was known of the histogenesis of sarcoma of the lungs. In 1879, Wagner described a neoplasm of the pleura which he called an endothelial cancer, which produced much discussion. The authorities differed greatly on the fundamental question as to what it was proper to call endothelioma. In tumors of the lungs it was very difficult to determine whether they took origin from the epithelium or from the endothelium. The endothelium had a very strong tendency to proliferate in many pathological conditions, especially in acute and chronic inflammations, and it was very difficult to distinguish a neoplastic growth from proliferation. Primary epithelioma of the pleura was sharply characteristic; the pleura was very much thickened, and especially the costal pleura. The pleura was hard and lacked its normal glossy surface. The microscope must establish the diagnosis. Quite extensive papillary growths of the pleura often occurred and, in all cases, there was an effusion, usually hemorrhagic in character, which filled the pleural cavities.

Cancerous erosions of blood-vessels were quite common, and caused metastasis; in twenty-seven of the cases referred to no deposits were found at all. The retroperitoneal lymph nodes were frequently involved. The mesenteric glands were involved in ten of the cases, the inguinal in four. Metastasis occurred in the liver eighty-seven times; the kidneys were involved in forty-nine instances, while the pericardium was affected frequently. In many cases attention would be called to the metastatic formation before the original tumor was diagnosed. Pericardial adhesions very frequently occurred, and the heart was often affected, the heart being invaded by direct proliferation. The aorta was frequently found to be surrounded by the tumor, but its walls were never taken up by neoplastic tissue. In only one case was it shown that the œsophagus was affected by metastasis. In a case of sarcoma the clavicle and hip were affected. In another case the appearance of a spontaneous fracture drew attention to such a metastasis; the primary sarcoma of the lung was only found on autopsy. Metastasis occurred in the brain in twenty-seven cases. The implication of certain nerves was quite common, the pneumogastric taking the lead in this respect. The diaphragm and peritoneum were frequently involved. In six cases the thyroid, in three cases the bladder, and in three cases the intestines were affected by metastasis.

Heredity was of small significance as a predisposing condition, but five cases being found in which this was positive. Habits and occupation were not found to be predisposing factors. So far as a predisposing cause existed among metal workers and the like, nothing of value was noted. Why women were less susceptible than men

was still unsolved. Traumatism as an etiological factor was given in a number of instances, but if any influence was exerted, it probably was simply as a stimulant to the neoplastic growth. Active tuberculosis was noted in thirteen out of thirty-one cases of sarcoma reported by Wolff, but he thought that it had only been proven that cancer and tuberculosis might exist at the same time.

A number of cases were recorded in which there were no symptoms. In looking over the clinical history of many cases, one was struck by the monotony of the symptoms, such as pain, cough, etc. The most frequent of the earliest signs was the cough, and every variety of cough was encountered. The character of the sputum was considered important in primary malignant neoplasms of the lung and pleura. Hæmoptysis and the prune-juice expectoration were found to be almost pathognomonic. In 158 cases no aid could be had in diagnosis from the character of the expectoration; in thirty-seven cases during the entire course of the disease there was not a trace of expectoration. In fifty cases there was more or less abundant sputum, but no trace of blood. The sputum in many cases contained gangrenous masses—green sputum. Persistent green sputum was strongly suggestive of sarcoma of the lungs. In thirty-eight cases the sputum was found to be bloody, in thirty-three cases it was constantly mixed with blood. Reliance could not be placed upon any findings of characteristic cells, so-called, in the sputum, and a diagnosis could only be made by an examination of the tumor particles expectorated. Hæmoptysis occurred very frequently, and this might be the cause of death; this danger was always to be borne in mind. Dyspnœa was frequently noted, the most excessive dyspnœa being due to obstructions of the trachea. Pain as an early symptom was noted in 121 cases, and this was commonly considered a gauge of the extent of pleural involvement. Malignant tumors of the lungs were not usually associated with cachexia. In one case which lasted four years there was a florid condition of the skin at the time of death. In many cases this might be marked, especially in sarcoma. Pleuritic effusion was one of the most common occurrences in primary sarcoma of the pleura and, as a rule, it was found to be perfectly clear, but gradually became bloody as the disease progressed. Microscopical examinations of the exudate often aided in the diagnosis. Many pressure effects were noted. The physical examinations of the chest gave results varying much in character. The physical diagnosis depended mainly upon the anatomical distribution of the disease. In some cases flatness was noted, in others tympanitic sounds were elicited. There were manifold variations. Intense dulness, often flatness, with a woody resistance in the upper part of the right or left lung, associated with abolished voice and breathing sounds, not extending to the apex, presented a group of symptoms which were fairly pathognomonic of malignant neoplasms of the lung and pleura. The one absolute and characteristic pathognomonic sign was the finding of the tumor elements in the sputum.

There was great difficulty in making a diagnosis between tuberculosis and tumor, for the clinical as well as the physical signs were found in both. Syphilis must be differentiated, as well aneurysm. The diagnosis of malignant disease of the pleura was not often difficult. The *x*-ray was of great value in diagnosing diseases of the chest. With a proper consideration of all the points in the history, and a careful physical examination, a correct diagnosis of malignant neoplasms of lung and pleura might be obtained in many cases; although such a correct diagnosis meant the death-warrant of the patient, it accrued to the benefit of suffering humanity.

The Nurse's Bureau.—Dr. A. Jacobi said that this bureau had been established for the purpose of accommodating physicians and the public at the same time, and it had been very successful. In the last Legislature of the State of New York, a law was passed that there should be no bureau of this kind continued without a license, and this license was a costly one. He did not think the Academy of Medicine should go into business of this kind; the Academy was an educational body and, therefore, it paid no taxes. If it paid such a license the City of New York would call upon it to pay taxes. The nurse's bureau was not founded for the purpose of making money and, therefore, he asked that a vote be taken to discontinue it. This request was unanimously assented to.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Ninety-Ninth Annual Meeting, Held October 24, 1904.

The President, Dr. Wendell C. Phillips, in the Chair.

Officers Elected.—*President,* Dr. Henry S. Stearns; *First Vice-President,* Dr. Floyd M. Crandall; *Second Vice-President,* Dr. Walter L. Carr; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. Edmund Prince Fowler; *Treasurer,* Dr. Charles H. Richardson; *Censors,* Dr. Wendell C. Phillips, Dr. William H. Park, Dr. H. Semour Houghton, Dr. Joseph Brettauer, and Dr. Egbert Le Fevre.

After the annual reports of the chairmen of the various committees had been received, a series of short addresses followed.

Recent Developments in Clinical Pathology.—Dr. Frederic E. Sondern said that the chemical and microscopical examinations as an aid in diagnosis and prognosis had received a large share of attention during the past few years, and that the refinement of the work demanded expert knowledge somewhat beyond what was acquired in our medical schools, and more elaborate outfits. The great difficulty to be overcome was the amount of time required by this work and, as a result, much of it was done by beginning practitioners of medicine, who were often insufficiently equipped, and by men who lacked clinical knowledge, and who were consequently unable to appreciate the direction in which to pursue their investigations. The publications on the subject were oftentimes faulty from the physician's point of view. Most men appreciated the fact that clinical pathology was of more of less value in diagnosis and prognosis, but, as in all other classes, there were extremes. It was reasonably plain that the practitioner who ignores to-day the microscope and test-tube is as short-sighted as the man who makes every diagnosis in the laboratory; the laboratory findings should only be considered a part, or as a support, in diagnosis. Dr. Sondern then considered but a few of the things which had undoubted merit. The differential diagnosis of chlorosis, anæmia, and pernicious anæmia, he said, was well understood by all. He referred to the present methods of determining the amount of coloring matter in the blood. Leukæmia was badly classified. Since the blood examination had become a routine matter, much regarding leukæmia had been published, and he hoped for a better classification of this disease. The Widal reaction in typhoid fever rarely gave positive results before the fifth day in bed. This made the test of less value in diagnosis in the early stages of the disease than had been hoped. The blood changes, as indications of inflammatory lesions had recently been studied, and were the subject of much discussion as an aid in diagnosis. Leucocytosis he believed to be largely dependent upon body resistance. Thus, given a well pronounced resistance, leucocytosis will appear in slight infections; on the other hand, given a poor resistance, little or no leucocytosis will appear in grave affections. He said he had been impressed with the fact that a differential count of the leucocytes was a far better guide as to the status of the inflammatory process; furthermore, leucocytosis with a differential count might be an indicator of body resistance. The examination of exudates and transudates had become a subject of extensive research. In the differential diagnosis of these, the older chemical methods were still much used. Urine analyses and attention to faulty metabolism were important in diagnosing eclampsia and puerperal tox-

æmia; also intestinal lesions and so-called rheumatism and gout. On diagnosing the varieties of nephritis there was much that was of value besides the presence of albumin and casts. In diabetic urine there were other facts that gave us a better insight of the patient's actual condition than the mere knowledge of the presence of sugar. Estimating the renal functional ability was of value to the surgeon. He said that Dr. Cabot had stated that, as a result of investigation, there was absolutely no value to be placed on the mere knowledge of the daily excretion of urea; that it was of no importance unless we had an accurate record of the intake. Dr. Sondern said that while there was a great deal to be said in favor of this, yet he thought Dr. Cabot's statement was too broad. But to speak of the number of grains of urea in a given ounce of urine which the patient might pass at a given time seemed to him to be of little or no value.

A Brief Report on Recent Progress in Bacteriology.—Dr. Wm. H. Park said that the results of the use of antistreptococcic serum were reported by a certain individual as being perfectly marvelous. On the other hand, the results in North Germany showed that it was of no value. He referred to the discovery by Mallory of a protozoon in the skin of patients suffering from scarlet fever; protozoa were undoubtedly present there; an examination of the fluid obtained by blisters demonstrated beautifully a great many of the protozoa-like bodies. With regard to dysentery, he said there was at the present day a majority of cases of summer diarrhœa not due to the Shiga bacillus, or the so-called acid varieties of bacilli. In from 50 to 80 per cent. of the cases no dysenteric bacilli were found. Again, they could be found in a certain number of normal cases. It should be remembered then that while the dysentery bacilli are present in many cases, still, in this climate, they are not present in all cases. The use of the serum in summer diarrhœas had proven to be of no value. With regard to the diagnosis of rabies, he said there were certain protozoan bodies found which were not found in any other disease. By means of them a quick and certain diagnosis might be made. He spoke of some interesting experiments made by injecting the sheaths of nerves with antitoxin. Also of the use of copper sulphate to remove certain algæ from supposedly contaminated water. It had been used at the Croton water shed, and it was of value.

Dr. Jacobsohn said that two years ago a doctor in the Melbourne General Hospital reported forty-eight cases examined for Widal reaction; there were forty-six reactions obtained, although none of the patients had typhoid fever. The cultures showed no typhoid bacilli, but the colon bacillus was found.

Fads in Surgery.—Dr. Howard Lilienthal said that the practice of medicine had been influenced in all ages by fads, yet as each new research made its appearance there were not wanting those who, failing to recognize its importance, set it down as a mere fad. Twenty-one years ago microbic infection and antisepsis in surgery were regarded as a whim. The fad for double oöphorectomies had passed, but the ease and safety with which the uterus might be removed was responsible for many unnecessary hysterectomies. Again, we had the spectacle of operators vying with each other as to who could remove the largest fibroid or myoma by way of the vagina in instances where the more surgical abdominal would be the more preferable. The artist in surgery will weigh each individual case, and will plan his operation without being carried away by his desire to gratify the vanity of the patient, as well as his own, in avoiding an abdominal cicatrix. Another fad was that of the surgeon who cannot palpate a movable organ without a desire to anchor it. The female right kidney was the great sufferer in this respect. Nephrotomy, single and multiple splitting of the capsule, and complete renal decapsulation had been urged upon the profession with an enthusiasm which was not easy to withstand, even in the face of theoretical objection. Operation should be reserved for those unfortunate ones who were not benefited by other treatment. The fad which would split off from general surgery the treatment and operation necessary at the natural openings of the body, called orificial surgery, was such a patent absurdity that time used in discussing it would be wasted. As to radiotherapy, when employed in cases of operable malignant growths, lying deeper than the skin, he said that this had been taken up and urged with more zeal than sense. The time for the employment of radiotherapy was after the operation and not before it. There was one general rule for the employment of any remedial agency, and that was, to use it only when old and tried methods failed to give satisfaction. Gradually, but surely, the novelty would find its proper place. He would not be understood as decrying anything that was new, but merely the taking up and urging with more zeal than sense, to which he would call a halt.

Business-Like Methods in the Practice of Medicine.—Dr. John S. Thatcher delivered this address. He said that in an observation which extended over twenty-five years, he believed that certain factors in medical success were certain qualities such as were admired in business men, and which helped them in reputation and success; he referred to such qualities as promptness, directness, thoroughness, and straightforwardness. There were few, if any, reputable occupations which offered a better field for vain pretension and misleading superficialities. There were many baseless theories and foolish fads that confronted us. The majority of the people of the world care to have the feeling that medicine is a science established by hard labor and that it is an art practised by the sweat of one's brow. Among the best gifts were energy and straightforwardness of character. The achievements in medicine depended upon the capacity for taking pains. A charming bedside manner was helpful and delightful, but it did not rank with the highest gifts or the most useful ones. Knowledge and judgment were on top. In medicine as in other branches of science it was the good results that we wanted. What was needed to-day was a businesslike way, and this was most efficient for both patient and doctor. Directness was most valuable; to practise medicine one should apply business principles. Do not lack in thoroughness. Directness and straightforwardness might make a good doctor out of bad material. In dealing with patients with serious illness, he thought that a knowledge of the worst was far better to the patient than the fearful uncertainty, and it would be better to tell them of the hopelessness of their disease. The ordinary man would rise to such an emergency and would be in a better state of mind than if he was possessed of this frightful uncertainty.

Post-Graduate Medical Instruction in America.—Dr. D. B. St. John Roosa said that post-graduate medical instruction really originated in New York City, because here it was organized. He reviewed the difficulties encountered in obtaining post-graduate instruction in continental cities, especially Berlin, because it was so unorganized and unsystematized. In Vienna it was somewhat better than in Berlin, because instruction was given in one place, and one did not have to wander all over the city to obtain what was wanted. London had been a dismal failure so far as post-graduate medical instruction was concerned, comparing it with Berlin and Vienna. Why Edinburgh did not make a success in post-graduate medical instruction seemed to be beyond the comprehension of man. Paris, on the other hand, remained magnificent, not only because of her fame in the past, but of her standing in the present. Post-graduate instruction was well organized in New York. All instruction was placed under one roof, and good men were obtained to teach in every department, with the result that from 750 to 1,000 graduates in medicine studied in the two post-graduate institutions in New York in one year. He said that there was a time when undergraduate instruction was threatened by the greater prominence of Philadelphia and Chicago medical schools; but this post-graduate medical instruction came on here with such enthusiasm of energetic men, that New York was saved and preserved

for her prominence in medical instruction on this side of the water. Post-graduate surgical instruction, he said, had come to stay, because it would always be needed. In Cologne, Frankfort, and other continental cities, post-graduate medical instruction had been organized after American methods, and we had been given due credit for it.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held October 17, 1904.

ALEXANDER LAMBERT, M.D., CHAIRMAN.

Address of Retiring President.—Dr. ALEXANDER LAMBERT thanked the association for twice electing him president, and for their hearty cooperation. It was with feelings of regret that he laid down the pleasant duties, profitable as well as pleasant. It was with pleasure that he turned over the office to his successor, Dr. Quinlan, and he asked for him the same hearty and cordial support.

Address of Incoming President.—Dr. FRANCIS J. QUINLAN congratulated the association upon its past successful history, and anticipated much for its future. In giving a retrospect he referred to the first medical book of the County Association, which was dated December 14, 1883. At the invitation of Dr. Austin Flint, a few medical friends of his were called together to consider existing conditions in the city regarding a code of ethics; they advocated the formation of an association composed of members of the profession who should uphold this code of ethics. The result of this meeting was the organization of the present New York County Medical Association. Much stress was laid on the old standard of ethics. Those men had to fight for their knowledge, and the men of to-day, in the hurry of modern life, did not realize how much indebted they were to the men of the past. The adulteration of drugs and of foods was then considered. He said that the lilterature on this subject was almost inexhaustible, and the public press brought this knowledge every day to our notice. Efforts should be made to stop these frauds. He recommended the establishment of a National Board of Health which should look after the sanitation of the country, the health of whose eighty-five millions of people was of such paramount importance. The study of dietetics he considered to be as important as the study of therapeutics. He referred to the several deaths that had occurred as the result of poisonous whiskey in this city; the Health Department and the Coroners had been called in, and the cause of death, from an analysis of the stomach contents, was found to be wood alcohol. Recently in Manchester, arsenic had been found in beer. Wine, beer, and milk had recently been found to contain boric acid and salicylic acid. Powdered alum had been found in baker's bread, rolls, and biscuit; this interfered with the digestive processes, and could even act as an irritant poison. The only remedy for these abuses was the enactment of uniform laws forbidding these ingredients, and making the examinations of foods obligatory. Boric acid should not be used in foods. In cream of tartar one grain of lead to the pound had been detected. In New York City some specimens of butterscotch had been found to consist of glucose and hard paraffin. Rice as it came from the fields was bright, but after standing it became dull and lusterless; this luster was restored by soaking the rice in oil or paraffin. Coffee from Brazil cost 12 cents a pound, while a combination of Mocha and Java cost 40 cents; only 3 per cent. of the coffee imported was of this latter variety. He called attention to the fact that twenty-one million barrels of patent medicine were sold each year. Jamaica ginger, in some instances, contained 90 per cent. alcohol. He referred to the advertisements found in the religious periodicals. Dr. Osborn of Yale College had asked that postal laws he enacted to stop the publication of such frauds. In concluding, the speaker referred to military sanitation, the achievements of Dr. Leonard Wood in Cuba, and the work of the United States Marine Hospital Service.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, Held in Cincinnati, Ohio, October 11, 12 and 13, 1904.

(Continued from page 716.)

SURGICAL SECTION.

Radical Cure of Hernia.—Dr. HAL C. WYMAN, Detroit, Michigan, read a paper on this subject. The problem of hernia had been so fully worked out in the inguinal and umbilical regions that there was nothing to do now but to find the hernial opening, and stitch it up so that the bowel would stay where it belonged in the cavity of the abdomen. In any case of intestinal hernia it was a fair presumption that the intra-abdominal space was not large enough to contain the intestines, and the abdominal walls were insufficient to embrace the abdominal contents. It was reasonable, then, to assume the surgical intervention for the cure of intestinal hernia should include measures to reduce the volume of the abdominal contents, and to increase the size and strength of the abdominal walls. Masses of omentum and part of intestines must sometimes be removed to make room; and flaps must sometimes be dragged in to supplement the insufficiency of the muscles and fascias. Suturing must be complete, absolute, and without the tension that damaged and destroyed any of the tissues. Scrotal skin and fascia might be sutured into the large hernial openings with gratifying results by making an entirely new place for impingement of the intestines that would otherwise protrude. Many patients with inguinal hernia might be permitted to get up when they felt able, with great advantage in educating the abdominal muscles to perform their offices, so that hernias did not occur.

The Typical Anatomieal Operation for the Radical Cure of Oblique Inguinal Hernia.—Dr. ALEXANDER MUGH FERGUSON, Chicago, contributed a paper on this subject, which was accompanied by numerous and beautiful illustrations. Dr. Ferguson described his method of operating on these cases, a full description of which may be found in the current medical literature. So far as he could determine, approximately 2,200 cases had been operated on by his method without the recurrence of hernia.

Dr. WILLIAM J. MAYO said that of 600 or more operations done in accordance with the Ferguson method, only three relapses had occurred, and he was uncertain as to whether these were really due to the Ferguson or Bassini operation.

Dr. H. O. WALKER considered the Ferguson method rational, and the results good. He had operated by this method over a hundred times, and had had no recurrence of hernia. He spoke of two cases in which he did a perineal prostatectomy, in addition to the operation for the radical cure of hernia at one sitting, with satisfactory results in both instances.

Dr. VAN BUREN KNOTT had been employing the Ferguson operation for some time, with the happiest results. He had had no recurrences.

Dr. EMIL RIES favored getting patients out of bed as early as possible after abdominal or hernial operations. He did not hesitate to let his patients get out of bed on the first or second day after operation, and had had no evil results therefrom. He had used the method of Kocher in a number of cases of inguinal hernia, the main point being inversion of the sac, and had had no recurrences following this method.

Dr. JOSEPH RILUS EASTMAN doubted the wisdom of allowing patients to get out of bed two or three days after an abdominal or radical operation for hernia, on account of the great strain from pressure on the aponeurosis of the external oblique. He preferred to keep his patients in bed from two to three weeks than take chances.

Dr. JOHN YOUNG BROWN preferred the Ferguson operation in cases of inguinal hernia, and while the results of it were not better than those obtained by the Bassini, he believed the Ferguson method was much simpler, inflicted less trauma, and therefore should be adopted. While he

had had no recurrences, he thought in a small percentage of cases recurrence would take place.

Dr. Thomas H. Manley said the Ferguson operation had come to stay, because it was attended with little or no danger to life. He had never seen a patient die from an operation for non-strangulated hernia. Notwithstanding the various methods that had been described, he was rather inclined to advise the method advocated by Lucas Championniere. The results following this method were satisfactory. In the last year he had seen the intestine slough after a Bassini operation, and strangulated hernia occurred after it.

Dr. A. J. Ochsner said the Ferguson operation contained the successful elements of a herniotomy. The operation should be done without injuring these tissues by suturing too tightly.

Foreign Bodies in the Esophagus.—Dr. Carl E. Black, Jacksonville, Illinois, reported two obscure cases of foreign bodies in the esophagus, in which a positive diagnosis was made by the use of the *x*-ray. He made extended remarks regarding the value of the *x*-ray in locating foreign bodies and assisting in their removal.

Spleenless Men; Report of Two Successful Cases of Splenectomy.—Dr. J. Henry Cartens, Detroit, Michigan, said that splenectomy was indicated in selected cases of enlarged spleen, but not in all instances. The first patient had pain and distress for a year or two in the region of the spleen, with gradual enlargement. There was sudden rapid growth within three months, filling nearly the whole abdominal cavity. Emaciation was marked. Blood examination showed destruction and irregular shape of red blood corpuscles. A probable diagnosis of malignant growth was made. Operation disclosed it to be a sarcoma. Operation was followed by complete recovery, and the blood was now normal. In the second case, the onset was gradual, and there was an enlargement for six months. Splenic anæmia was diagnosed. The leucocytes numbered only 1,200. There was extreme debility. Operation was performed, followed by complete recovery. The blood was now normal, and patient had gained 96 pounds in weight since leaving the hospital fifteen months ago.

Operative Work in the Ureter Through the Lewis Catheterizing and Operative Cystoscopes.—Dr. Bransford Lewis, St. Louis, Missouri, in a paper with this title, considered the subject in its three relations: As a practical and reliable procedure, as a diagnostic measure, and as a therapeutic measure. After alluding to his operative cystoscope, and the instrumental equipment connected with it—ureter forceps, scissors, dilators, irrigating attachments, etc., the author considered diagnosis and therapy. The first case mentioned was that of a male, in whom the diagnosis established was that of inactive left kidney, while the right one was not only carrying on all the kidney functionation present, but contained numerous calculi of various sizes. Ureteral manipulations through the operative cystoscope removed a dozen or more small calculi, which he exhibited, but could not secure the escape of the largest, which was removed by lumbar incision. The patient recovered, notwithstanding the fact that the only kidney functionating was opened and cleaned out. The second case related was one in whom small calculi had been removed by similar means in two sittings, a year apart, the stones being exhibited. The third case was one in which there had been severe and exhausting symptoms of ureter calculus, of sixteen years' duration. There were numerous consultations and oft repeated attacks, occasionally requiring the prolonged administration of chloroform. This patient was finally and definitely relieved, and had had no recurrence of the pain for nearly a year. A case of definite and severe stricture at the lower end of the ureter had been completely relieved by dilating methods, carried out through the operative cystoscope, in successive sittings, and without complaint on the part of the patient, who was a very nervous woman. Some of the difficulties and disappointments liable to be met with in this work were alluded to and suggestions given for avoiding them.

Perineal Prostatectomy.—Dr. Joseph Rilus Eastman, Indianapolis, said that if all prostatectomies were made as soon as the symptom of residual urine made its appearance, the mortality would be practically *nil*. Too often the reason for the application of the Bottini method, perineal cauterization, or other palliative procedure was that a case had been permitted to drag along with the catheter until advanced age, general sclerosis, or kidney complications, forbidding prostatectomy. The conservative operation of Hugh Young should be the one of choice, if applicable. It consisted, as was now generally known, in making a sagittal incision closely parallel to the median raphé, through each lateral lobe, and shelling out one lateral lobe at a time, preserving the median bridge containing the ducts. After the removal of the lateral lobes, the third lobe was depressed into a lateral defect, and likewise shelled out. After enucleation, Young united the separated margins of the levator ani to the end, that the gauze packing might not press upon the rectum and favor fistula formation. Clinically, the perineal operation had been proven to be the safest. The perineal route was the least bloody, since it admitted of a complete exposure of the prostrate, thereby making it easier to shell out the prostrate in the essential line of cleavage. After perineal prostatectomy, the bladder *bas fond* was provided with low, level drainage, instead of the up-hill or siphon drainage of the suprapubic operation. It would certainly be conceded that the danger of wounding the ejaculatory duct in any conservative operation would be lessened if the perineal operation be chosen.

Pathological Changes Resulting From Prostatic Enlargement.—Dr. Charles E. Barnett, Fort Wayne, Indiana, said there was still plenty of room in the field of research for the etiological factors in prostatic enlargement. Perverted orchicism and inflammation seemed to be the most logical causes. The former produced hyperplasia, on account of a lack of orchoprostatic equilibrium. Inflammation started true adenomyoma, either or both, by stimulating the embryological matrix, on account of the infected acini, and there was a pathological evolution tumor metamorphosis from a fibro-myo-adenoma to an adeno-myo-fibroma. The pelvic fascia was responsible for all future pathology after enlargement began, on account of its inability to accommodate itself to the displacements that occurred. Anatomical study of this fascia was especially hard for the student, on account of the multiplication of synonyms found in text-books. The distorted neck of the bladder started pathological changes which finally reached the kidneys, and if not stopped by operative procedure upon the prostate would destroy them.

Dr. G. Frank Lydston thought the profession at large had accepted perineal prostatectomy as the operation of election, although there were certain cases that should not be dealt with by this route. It was the most direct route, where it was practicable to adopt it. In many instances it was imperative to treat patients palliatively until one was positive that the tumor was not only increasing in size, but was causing urinary obstruction.

Dr. E. M. Gilliam narrated two cases of hypertrophy of the prostate upon which he had operated, and in the after-treatment recommended placing the patient in the Fowler position.

Dr. H. J. Scherck said there was a class of cases in old men whose bladders contained a more or less amount of residual urine, irrespective of the condition and size of the prostate. The condition seemed to be more of aton of the bladder walls than the effect of the enlarged prostate.

Dr. Bransford Lewis pointed out that there was no particular operation which fulfilled all the indications in cases of hypertrophied prostate. He detailed the case of a man, seventy-one years of age, who he believed would not have withstood a prostatectomy at any time. The patient had a stone in his bladder as large as a fist, with a ragged

edge. The author did suprapubic lithotomy, removed the stone, drained, and also performed a Bottini operation. The patient was relieved of a fistula that had existed, and had completely recovered.

Dr. F. F. Lawrence said that if surgeons could convince the general profession that hypertrophy of the prostate was a surgical disease, the mortality now attending prostatectomy would immediately decrease, as it had done from operations on cases of appendicitis, ovariotomy, and other surgical affections.

Dr. H. O. Walker had operated by the suprapubic route over twenty times, and had lost one patient. At the same time he preferred, wherever practicable, to do perineal prostatectomy. He removed a prostate suprapubically that weighed seven and a half ounces.

Plastic Surgery of the Urethra.—Dr. G. Frank Lydston, Chicago, read an interesting and valuable paper on this subject, in which he described the methods he had found most satisfactory in his own cases.

Therapeutic Value of Radium.—Dr. Myron Metzenbaum, Cleveland, Ohio, narrated his personal observations in the clinical uses of radium. He discussed the physiological action of radium of low activities contained in hermetically sealed tubes when placed on ulcerated areas and on the unbroken skin for thirty-five minutes; also the pathological condition resulting from placing radium of high activity contained in hermetically sealed tubes on the unbroken skin for long periods of time. The therapeutic results obtained by using tubes of radium of low activity and coarse were as good in the treatment of lupus, rodent ulcer and small epithelioma as those from the use of radium of high activity and great expense. The author reported and showed photographs of three cases of lupus, and one each of rodent ulcer and epithelioma that had apparently healed by the aid of radium rays. Photographs made by the *x*-ray and by radium were exhibited, showing that the latter had comparatively little value in the skiagraphy of bone as compared with the *x*-ray. He pointed out the results obtained by suspending hermetically sealed tubes in various solutions, showing that the same had not been rendered radioactive, and therefore that they had no special therapeutic value.

Two Cases of Pancreatic Cyst.—Dr. Van Buren Knott, Sioux City, Iowa, pointed out the physical signs of these cysts and the difficulties which sometimes attended their diagnosis. He showed how the surgeon might be misled by the symptoms. He discussed the method of treatment, made a comparison between incision and drainage and excision, and reported two cases which presented widely different symptoms, physical signs, and morbid influence, treated by different methods. Comparison of these two cases of cysts of the pancreas had been extremely interesting to him, and revealed many striking differences. The more important of these he briefly mentioned as (1) the difference in location and anatomical relations of the tumor. (2) Neither cyst occupied the usual position for such tumors, *i.e.*, somewhat to the left of the median line. (3) Neither was a so-called false cyst of the pancreas, which was a localized collection of fluid in the lesser peritoneal cavity, but each involved the tissues of the pancreas alone. (4) The appearance in the first case of symptoms of disturbed function long before evidence of cyst formation could be detected, while such symptoms remained entirely absent in the second case, even after the tumor had attained great size. (5) The even spherical form of the pancreatic distention in one case, and the peculiar sausage-like tumor in the other, gradually expanding into a spherical termination. (6) The fact that the patient, who had much the less complete operation, *i.e.*, incision and drainage, had a much smoother and more rapid recovery than the one in whom the tumor had been almost completely removed. (7) The involvement of the stomach in the first case rendered possible the wounding of its walls during the puncture of the cyst, as the true nature of the stretched, flattened and congested viscus was recognized with some difficulty. In the second case no such accident was possible. (8) The accumulation in the walls of the first cyst of a peculiar sticky, grayish, ash-like deposit, while the lining membrane of the second tumor was clean and smooth. (9) In neither case was the sallow, dry skin, said to be characteristic of cysts of the pancreas, present.

Tenotomy of the Tendo Achillis in Partial Amputations of the Foot and in Fractures of the Tibia and Fibula.—Dr. J. P. Webster, Chicago, read a paper on this subject, in which he drew the following conclusions: "(1) It is a well-established clinical fact that after tenotomy of the tendo Achilles (when the foot is kept at rest) the process of repair takes place, and satisfactory functional use of the foot is the result. (2) It is much easier to maintain the foot in the exaggerated flexed position after the tenotomy of the tendo Achilles than with any form of splint, anterior or posterior, metallic or plaster. (3) There is much less pain, as the foot and ankle joints are placed at absolute rest. (4) When the patient commences to walk, none of the resistances of the contracted heel cord is present, so that there is but a slight limp. (5) In oblique and comminuted fractures of the tibia, there is much less danger of overriding of the fragments of bone, after a tenotomy. This greatly simplifies the care of the leg and helps to prevent deformity."

Physiological Purposes of the Mamma.—Dr. Thomas H. Manley, New York, discussed the coarse and fine anatomical elements of the mamma in their bearing on some of its pathological affections. He drew the following conclusions: "(1) The mamma is a highly organized and, structurally, a most complex organ. (2) Its functions are manifold. It is an essential and integral part of the generative system. Intermittent in function, like the testes, total ablation, like double castration, makes its impress on the sensorium. (3) Very frequently degenerative or pathological changes begin in a single isolated lobe, about twenty of which are in each breast. In all non-malignant affections, radical measures should be limited, as far as possible, to the affected area or lobe. (4) It is only in malignant disease of a progressive type and life is imperiled, that total sacrifice of the breast is justifiable. (5) Inasmuch as the functions and purposes of the axilary lymph ganglia are yet imperfectly understood, and their removal, quite invariably enhances the risks of operation, involves a wide mutilation of the chest walls, and always leaves more or less impediment in shoulder action, or even at times a painful tumefied limb, it is only as an extreme and exceptional measure that their complete extirpation should be practiced."

Intestinal Surgery, with Remarks on Technique.—Dr. John Young Brown, St. Louis, said there was a class of abdominal cases which might justly be considered acute, for the reason that the indications for immediate surgery were mandatory, and in which the mortality largely depended upon the time of operation and the technique of the work. He discussed (1) penetrating gunshot and stab wounds of the abdomen; (2) severe abdominal contusions associated with rupture of intestines or other visceral injuries; (3) strangulated hernia, confining himself as nearly as possible to a consideration of the operative technique, citing cases in point.

Gastroenterostomy.—Dr. William H. Wathen, Louisville, in this paper described all the pathological conditions indicating the necessity for stomach drainage by the several methods that had been practiced for this purpose. He said pyloric divulsion had proven unsatisfactory, seldom gave permanent results, and sometimes increased the trouble. Pyloroplasty and its modifications had given better results, but the operation was seldom indicated and was practically obsolete. Gastroduodenostomy, and especially the modification by Finney, was theoretically ideal, and in properly selected cases gave excellent results, but

it was often impracticable because of adhesions of tumors, and could not be generally adopted; its simplicity could not recommend it, because gastroenterostomy might be performed as easily, as quickly, and with a mortality as low, and was applicable in nearly all cases. Wölfler's anterior anastomosis and von Hacker's posterior anastomosis, with their modifications, were the two methods generally adopted, but Raux' method of cutting the intestine across, implanting the distal end into the stomach, and the proximal end into the side of the distal end was theoretically ideal, and avoided regurgitant vomiting, but it was difficult and prolonged, and if universally accepted would have a mortality that would be prohibitory. Gastroenterostomy by the surface to surface anastomosis of the stomach and the jejunum was applicable to the greatest number of cases, and might be performed in nearly any condition requiring stomach drainage. Anterior gastroenterostomy as an operation of election must very soon become obsolete, and would finally be accepted only where an operation was necessary to give temporary relief, or where the posterior operation was contra-indicated, because of adhesions and the feeble condition of the patient that demanded a quick operation. The ideal operation of election must eliminate the intestinal loop, and this might be done by the posterior method, by attaching the jejunum very near its origin under the transverse meso-colon; the bowel incision might then be made longitudinally or transversely, but was usually made in a longitudinal direction, Kocher and Mikulicz making a transverse incision. This method was preferable if the opening into the bowel could be made large enough to permit of continued unimpeded drainage, but the anastomosis was more difficult than in the longitudinal bowel incision. Posterior gastroenterostomy was now the accepted method with Robson, Mikulicz, Kocher, Czerny, Moynihan, and Mayo, with no higher mortality than the anterior method, with nearly an absence of regurgitant vomiting and other immediate complications, and with ultimate excellent results in drainage, the gastrojejunal opening seldom contracting enough to induce pathological condition. The McGraw ligature in the anterior method gave good, immediate results, but we could not judge correctly of the ultimate results in the potency of the gastrojejunic opening, and the ligature had probably not been tested in the posterior method. The Murphy button had the advantage of being quickly applied, but except in selected cases possessed no advantages over the suture, and was more frequently followed by complications.

The Indications and Limitations of Various Operations on the Gall-Bladder.—Dr. Charles A. L. Reed, Cincinnati, reviewed the various operations usually performed for the relief of surgical conditions of the gall-tract, summarizing them under the heads of cholecystotomy, cholecystectomy, cholecystenterostomy, and choledochotomy. He recounted his experiences during the last fifteen years, first with cholecystotomy, and cited cases to show that operation had distinct limitations, and urged that it ought not to be done in cases in which prolonged drainage was required, or in which there was a demonstrable permanent obstruction in the common duct, or in cases in which there was reason to suppose that such obstruction might develop. He insisted that the gall-bladder exercised functions of importance in the human economy, and that consequently it ought not to be removed without adequate cause. He recognized as legitimate indications for cholecystectomy conditions of atrophy and malignant degeneration of the gall-bladder and cases in which benign neoplasms caused practical obstruction of that viscus; but insisted that the operation ought never to be done when the gall-bladder could be restored to functional integrity with safety to the life and health of the patient. He urged that cholecystenterostomy should be considered the operation of choice in all cases in which the gall-bladder and a desirable segment of the intestinal tract, preferably the duodenum, the ileum, or the jejunum, in the order mentioned, should be approximated, and in which drainage was demanded for accumulations within the gall-bladder of whatever character; for occlusion of the common duct, or following operations upon it; for cholecystitis, in which the gall-bladder could be safely left *in situ*, and in all chronic fistulæ of the gall-bladder. It ought, also, to be employed to complete an anastomosis in cases in which nature had attempted to accomplish the task by the formation of firm adhesions between the gall-bladder and the intestines.

Ectopic Pregnancy.—Dr. F. F. Lawrence, Columbus, Ohio, reported cases of ectopic pregnancy. In ectopic pregnancy the death rate should be lower than in appendicitis, providing the surgeon got the cases before rupture. The diagnosis of tubal pregnancy before rupture should be made with as much or greater certainty than could a normal pregnancy before the third month. The fact that a tubal pregnancy was allowed to go on to rupture was a reproach to obstetric practice, first, because of indifference or carelessness, which prevented proper investigation of the case early. This might be on the part of the patient or physician, but the real fault lay in the indifference to obstetrics which had permitted women to look upon pregnancy as a simple matter, and not one demanding the attention of skilled service except in complicated labors. In unruptured cases the tube could be more safely removed through abdominal incision. In ruptured cases he was convinced that it was often very unwise to attempt to remove a patient to a hospital. The chances of infection in her home could be more readily overcome than the danger of increasing hemorrhage by handling. In all cases of extrauterine pregnancy, tubal disease, which was bilateral, seemed well established. The danger of a catastrophe in case the unaffected tube was left was therefore great, unless that tube be safely obliterated. Absorbable ligature was not a safe material to use for obliteration. Silk of large size only should be used. The better practice was to remove both tubes, retaining the ovary, if possible.

Etiology of Ectopic Gestation.—Dr. H. B. R. McCall, Kansas City, Missouri, read a paper on this subject, in which he discussed the genealogy of ectopic gestation relative to evolution. He submitted a classification, reported cases, and made a plea for early diagnosis, and operation, with special reference to etiology and diagnosis.

Brain Abscess of Otitic Origin.—Dr. George F. Keiper, Lafayette, Indiana, reported cases of brain abscess of otitic origin, and made some observations concerning brain abscess in general.

Foreign Bodies in the Cornea.—Dr. Dudley S. Reynolds, Louisville, Kentucky, said that injuries of this character should be classified according to the depth of penetration and extent of surface. The foreign bodies should be classified as metallic, ligneous, vitreous, and calcareous. Of whatever character they might be, no kind of foreign substance should be left long in the cornea. Where the epithelium alone was involved, the injury should be classified as severe. Wounds penetrating the anterior elastic layer, even though of very limited extent, should be classed as grave. Those which penetrate through the cornea should always be regarded as perilous. Treatment of the serious, the grave, and the perilous varieties should conform with some general preconceived plan.

The Transverse Fascial Incision for Operations in the Pelvis.—Dr. Emil Ries, Chicago, contributed a paper on this subject. In order to gain reliable fascial protection for incisions for pelvic work, it was desirable not to have to incise the fascia in the median line. Pfannenstiel's method was a useful improvement where the organ or tumor to be removed was not large. It began with a transverse incision through skin, fat, and fascia. The fascia was then dissected up from the recti and raised as a flap with fat and skin. The recti were then separated and peritoneum incised in the median line. After the operation in the pelvis was finished, the peritoneum and recti

were sutured in the median line, the fascia and skin transversely. The author had used the incision for various operations on the tubes, ovaries, uterus, appendix, and reported favorable results.

Suppuration in the Nasal Accessory Sinuses.—Dr. J. A. Stucky, Lexington, Kentucky, pointed out the importance of early recognition of suppuration of nasal accessory sinuses. Frequent peculiar anatomical inter-relationship of the different sinuses, when involved in suppurative process, rendered the symptoms obscure and misleading. Suppurative products might exist in latent form, giving rise to no local symptoms, and eventually resulting in systemic infection. Chronic inflammation in a closed cavity had a tendency to pus formation. He reported fatal cases, due to absorption of pus or the invasion of suppurative inflammation through the optic foramen or holes in the cribriform plate to the base of the brain. The sequelæ of chronic suppuration of any accessory sinuses were frequently due to some form of neurasthenia and migraine. An increased number of cases were probably due to la grippe, pneumonia, and strenuous indoor life. The treatment was the same as for pus formation in any other part of the body—that is, free drainage. The middle turbinate most frequently caused obstruction of natural openings or a hindrance to free drainage, and the early removal decreased the necessity for more extensive and radical operation later.

Strictures of the Urethra.—Dr. A. Ravogli, Cincinnati, Ohio, said that urethral strictures were affections of localized tracts of the mucous membrane and of the submucous layer of the urethra, resulting often from gonorrhœa, and not rarely from trauma or from traumatic urethritis. The symptoms were mostly local, but at times they might be the cause of general symptoms and of neurasthenia. Strictures were of different varieties, spasmodic and organic. The organic strictures were to be divided into wide and narrow, the latter being the result of the former. Both were the cause of impairment of micturition and of the production of inflammatory symptoms of the genito-urinary organs. Strictures were somewhat diminishing in their frequency, and this must be credited to the recent method of treatment of gonorrhœa. In their treatment, one might expect a great deal of benefit from systematic dilatation and from remedial applications, but in some very serious cases external urethrotomy was imperative.

The Perilous Calms of Appendicitis.—Dr. Robert Wallace Hardon, Chicago, read a paper on this subject, in which he presented the following conclusions: "(1) Defervescence of symptoms and apparent better condition of the patient do not always mean recovery, but may be the forerunner of a dangerous condition. (2) As there is no specific for the disease, no matter what treatment is used, the one who procrastinates should shoulder the responsibility for the death. (3) When a clear diagnosis is made, but one treatment should be advised, that of operation as soon as possible under the conditions, or the golden opportunity may be forever gone. (4) The physician who does not explain the great dangers of delay and the small comparative danger of operation is doing his patient a serious injustice which often leads to fatal results. (5) Operation at the proper time usually greatly shortens convalescence, and eliminates all danger from this cause thereafter. (6) Procrastination is the greatest cause of surgical death, operation often being performed as a last resort when little hope of recovery exists."

The Prevention of Appendicitis.—Dr. William M. Harsha, Chicago, stated that from available figures it would seem that this disease was more frequent in America than elsewhere. This was on the assumption that the mortality rate was much the same in England, Germany, and France, where modern methods of medical and surgical treatment were practiced, and where statistics were or should be reliable. In England and Wales, with a population of about 33,000,000, there were 1,244 deaths from appendicitis and perityphlitis in 1901, or 38 per million. In 1902 there were 1,485 deaths, or 45 per million. In Illinois, with a population of about 5,000,000, there were in 1903 471 deaths from appendicitis, or 94 per million. In Chicago alone, which represents nearly two-fifths of the population of the entire State, there were 249 deaths in 1902, and 260 in 1903, being at the rate of 140 per million. The same high death rate was approximated in other cities of the United States, especially in similar latitudes. New York City had, in 1903, 439 deaths, or 123 per million. Statistics of deaths from this disease in various cities, both at home and abroad, were given. Considering the causes that might be influenced by treatment, the author believed errors of diet were the most frequent. The disease occurred most frequently at the age and in the sex in whom faulty habits of eating and errors of diet were most common, from ten to thirty years. It was common to see attacks follow an immoderate meal, or the taking of indigestible articles of food. If one had transgressed in either of these ways and felt the approach of an acute digestive disturbance, the rational treatment was the prompt evacuation of the whole digestive tract and strict recumbency. Cholera morbus ushered in many cases of appendicitis, which were regarded as the primary trouble. The acute digestive disturbance, irritating the mucosa, was followed by stenosis of the base of the appendix and the infection ensued. This he had observed formerly in a considerable general practice. While fecal concretions or foreign bodies were less frequent causes of appendicitis than was formerly supposed, they caused probably ten per cent. of cases. As to treatment, the individual case must be considered by itself, its etiology carefully studied, as well as any peculiarity, and treatment adapted accordingly. In one case it would be necessary to regulate the habits of eating, in another to cultivate immunity from colds or proper habits of exercise, while digestive disturbances of various kinds would require attention in others. In all the proper hygienic conditions should be secured to keep the vital resistance up to the highest point. During the past six or seven years he had advised these measures as preventive after one attack in which there had been no operation, and so far as can be known, he believed recurrence had not occurred in over twenty per cent., most of these being in young people, partly because of the greater frequency in the young, and in part he believed because of lack of intelligent coöperation on the part of the patient. The consensus of opinion was that more than 50 per cent. of the cases not operated upon recurred.

The Mortality of Appendicitis.—Dr. Channing W. Barrett, Chicago, read an interesting statistical paper on this subject, which was accompanied by a series of tables. Table No. 1 showed that Chicago still had a mortality in appendicitis about equal to .01 of the mortality from all causes. Table 2 showed that the percentage of female mortality from appendicitis varied very little from the percentage of female mortality from all cases, and that appendicitis was to be looked for as common in the female, notwithstanding the old belief that it was rare. Table 3 showed the greatest mortality at the best period of life, early adult life, the greatest number dying at any one year of age being 22 at the age of 19, the average age for all deaths being 26.54 years. Table 4 showed that leaving out the chronic cases the average duration of the disease in the 372 cases in which the time was mentioned was 8 33-76 days. Murphy's mortality cases showed that the average time after operation until death was 2.8 days. This demonstrateed that this vast number of fatal cases were operated upon at the end of the sixth day, while all authorities conceded that an operation on the first or second day was safe and desirable. Table 5 showed that the most frequent cause of death from appendicitis was suppuration of the appendix, caused by perforation, gangrene, or passage of the infection through the wall, and peritonitis; and, further, that adhesions and obstruction were common. Many cases did not have the advantage of hos-

pital treatment or an operation. An early diagnosis was most desirable, yet the Bureau of Vital Statistics considered that a diagnosis was not made at all in 105 cases; a few of the remainder were made by the Coroner. Some were made post-mortem, and one could never know how many were made too late for any operation to save life. The long, but only partial, list of vague diagnoses copied from the death certificates showed that in all probability some cases escaped detection. The author submitted the following conclusions: "(1) An early diagnosis is of the first consideration. (2) All troublesome appendices should be removed without waiting for an acute attack. (3) All acute cases should be dealt with surgically in the interval between the onset of appendicitis and the dangerous rupture, without waiting for pus outside the appendix, for peritonitis, for adhesions, or for a possible but remote interval. (4) Cases of perforation or gangrene, with localized abscess, should be operated with drainage or removal of the appendix, according to the judgment of the operator. (5) Cases with perforation or gangrene without a wall of adhesion are in still greater need of an outlet for the infection to lessen the tendency of infection to travel inwards. (6) Price, Murphy, Hawkes, and others have shown a better percentage of recovery by the operative treatment of acute perforative peritonitis. (7) A case of acute appendicitis should be operated upon at any time if the patient's condition will admit of an operation, unless the case is rapidly and beyond a question of doubt convalescing. In this latter case we should wait until all acute symptoms have passed. (8) Healthy appendices should be left alone. (9) Proper treatment does not contraindicate the use of stomach lavage, or the withholding of food, and when proper, these things should be employed, with or without operation. (10) Life is not the only consideration. The time of cure and after conditions are important. A case going through an acute attack without operation is saved by the adhesions. Adhesions are life-saving for the time, but they may be death-dealing afterwards. The waiting treatment favors adhesions; early operation avoids them. An early operation sends the patient home in from ten days to three weeks. Twelve cases treated by the rest treatment, reported in the *Journal* of the American Medical Association, June 22, 1902, show an average of 60 7-12 days from the onset of the disease to the discharge of the patients from the hospital."

Remarks on the Etiology of Fissure in Ano.—Dr. J. Rawson Pennington, Chicago, said that a fissure might be located at any point in the circumference of the anal canal. Its most frequent location, however, was near the posterior median line. No satisfactory explanation for this fact had been given; neither had any one proffered a satisfactory reason why it occurred in the anterior quadrant in less than one per cent. of the cases in males, and in more than eight per cent. of the cases in females. It seemed to the author that the theories usually taught and accepted as the cause of this disease were, at least in many cases, erroneous, and that we should have a more comprehensive etiology. He regarded the location of the ulcer as anatomical, and depended principally upon the support given to the tissues of the anal canal by the sphincters and levatores ani muscles. When the canal was over-distended, the dorsal surface received the least support from these muscles, the anterior the next, while the sides received the greatest. At the terminal portion this relative support is due to the difference in the distance between the posterior commissure and the tip of the coccyx, the origin of the external sphincter, and the tendinous center of the perineum, its insertion and the anterior commissure. Because of this difference, the posterior fibers of the muscle are more deployed than those of the anterior. Hence, when pressure was made from within outwards it was obvious, since muscle fibers were easier separated or split than broken at right angles, that the weakest point was at or near the anterior commissure. This latter point was weaker in women than in men. The lateral quadrants or sides received the greatest support from this muscle. Anatomical conditions and relations, almost identical with these, existed between the levatores ani and the proximal portion of this canal. Therefore, when this canal was placed under sufficient stress to rupture its tissues, the tear, all things being equal, should occur first on the dorsal surface, as it received the least muscular support; second, on the anterior surface, as it was the next weakest point, and, third, or last, on the sides. This was the sequential order in which the respective tears of this canal should and do occur, and they not only corresponded with the weakest points in the muscular cylinder that surrounded and supported these canals, but with the statistics of the sequential location of fissure in ano.

NEPHRECTOMY FOR TUBERCULOSIS OF THE KIDNEY, WITH A REPORT OF FOUR CASES.*

By HIRAM N. VINEBERG, M.D.,
NEW YORK.

ADJUNCT ATTENDING GYNECOLOGIST TO MT. SINAI HOSPITAL.

I FEEL that I ought to offer an apology for coming before you with a paper based on so small a number of cases. But as the series, small though it may be, bring out prominently some important points on the subject of renal tuberculosis, I venture to present them in the hope that they may excite profitable discussion.

Renal tuberculosis is of especial interest to the gynecologist for several reasons. In the first place, it is a legitimate expansion of his specialty, (2) it is a disease most frequently met with in the female sex, (3) it is a disease which the gynecologist not infrequently is the first to detect among the cases sent to him for intractable cystitis presumably due to some uterine disorder.

The gynecologist, from the nature of his work at the present time, can no longer be considered as an amateur in the domain of renal surgery. He who has, I may almost say in his daily work, to lay bare the ureters along their whole pelvic length, perhaps excise a portion of the bladder, implant a divided ureter into the bladder, or anastomose the two cut ends of the ureter, or be forced to remove a kidney at the termination of a difficult pelvic operation, ought surely to be able to perform any procedure upon the kidneys that surgical principles demand. And thus it happens at the present day that uretral surgery is linked with the names of several gynecologists, and when kidney surgery is mentioned, the names of at least two gynecologists stand out in great prominence. I have reference to two of our distinguished Fellows, Howard A. Kelly and G. M. Edebohls, both of whom have done pioneer and yeoman work in that direction.

It is not my purpose to enter, at any length, into the symptomatology or diagnoses of renal tuberculosis. It will be my aim rather to dwell on some of the salient points of the disease that may be of especial interest to us as gynecologists, and to discuss some of the points that are still *sub judice*.

I have already stated that renal tuberculosis is more frequently met with in women than in men. Of Israel's[1] twenty-six operated cases, sixteen (61.5 per cent.) were in women; in Facklam's[2] collection of statistics nearly the same percentage of the relative frequency in the female sex obtains. Facklam collected 103 operative cases, seventy-three (70 per cent.) of which were in women.

At the recent German Congress of Surgery, Kümmell[6] of Hamburg, reported having operated on forty-eight cases of renal tuberculosis, only fifteen of which were in the male sex. Krönlein, at the same meeting, reported fifty-one cases of renal tuberculosis, all of whom but thirteen were women. But it must not be inferred from these figures, as Israel remarks, that tuberculosis of the kidney actually occurs more frequently in women than in men. Statistics collected from autopsies show no such disproportion between the two sexes. On the contrary, the tables of Morris,[4] Tilden Brown, Fagge, and Watson, based on the findings on the autopsy table, showed that men are more frequently affected than women.

What the figures of the operated cases, however, do unmistakably demonstrate, is that primary renal tuberculosis is more frequently met with in the female than in the male sex. In men the disease is generally of the ascending variety,* starting out from the genital organs, and hence is not so amenable to surgical intervention. But in women such an association does not exist, the genital and urinary are two separate and distinct systems.

Israel was able to find only one case in the literature in which apparently a genital tuberculosis was associated with a renal tuberculosis. The patient in that instance was operated upon for a tuberculous pyonephrosis, and two years later had her tubes and ovaries removed for tuberculous disease. In the thirty-five cases collected by Hunner[3] in the services of Howard A. Kelly and his associates in Baltimore, an instance is also related where Dr. Kelly had to operate some years later for tuberculous adnexa.

According to Israel,[1] renal tuberculosis is most frequently met with in the third and fourth decades of life; 80 per cent. of his operated cases occurred in those decades. He had only one case in the fifth and one case in the sixth decennium. In Hunner's collection, fourteen cases occurred in the third decade, and twelve cases in the fourth decade. The ages of three of my patients were forty-six, forty-seven, and forty-eight years respectively. The age of the fourth patient was thirty-nine years. It would appear, therefore, that the age of my patients was unusually advanced.

Renal tuberculosis is usually very insidious in its course, and may exist for a long time without giving rise to any appreciable symptoms. The first symptoms to manifest themselves, in the majority of cases, are those referable to the bladder, and hence it is that the patients are treated a long time for cystitis, and no suspicion of a kidney affection is entertained. Three of my patients had been treated for months for cystitis, and one patient (Case IV.) had been an inmate of several prominent hospitals for a period extending over three years, and at no time was a tuberculous lesion of the bladder or the kidney suspected. There is nothing characteristic about the bladder symptoms to differentiate them

*Read at the Twenty-ninth Annual Meeting of the American Gynecological Society, Boston, May 24, 25, 26, 1904.

* Recently the theory of ascending tuberculosis, even in mules, has been strongly disputed, the opponents of this theory holding that it is impossible for the tubercle bacilli to travel upwards against the current.

† Since writing the above I have operated upon another case of tuberculosis of the kidney which had been treated for nine months for supposed cystitis.

from a non-tuberculous cystitis, excepting in a manner to which I will refer later.

The urine is usually acid, contains a varying amount of pus, some leucocytes, and, according to Israel, some red corpuscles. Casts are seldom found, and some authorities hold that the absence of casts is characteristic of renal tuberculosis. Tubercle bacilli are found in 59 per cent. of the cases that are complicated with tubercular cystitis. Hunner maintains that they can always be found if daily examinations are made for a week or longer. In two of my cases, daily examinations for tubercle bacilli were made for a longer period than that, with a negative result. In only one of the cases (Case II.), in which there was a well-founded suspicion that the disease was primary in the bladder, did we find tubercle bacilli in the urine.

A cystoscopic examination may be of great service in making a diagnosis. In some cases an ulcerated area about one of the uretral orifices may be seen, or the mouth of the ureter may be swollen, presenting a nipple-like projection. In others again, there may only be a patch of redness surrounding the orifice, or a red streak extending from the orifice on to the bladder wall. Again, distinct tubercles may be seen in areas of greater or less size scattered over the bladder. Ulcers of varying size, with a grayish deposit, are occasionally seen. In some cases the bladder is so irritable that the greatest patience has to be exercised before a satisfactory examination can be made.

Some authorities, notably Hurry Fenwick and Willy Meyer, look upon ulceration about the orifice of one ureter, with the rest of the bladder wall being healthy, as pathognomic of tuberculosis of the corresponding kidney. The sign is an important one, but too much weight should not be attached to it in women, as is shown by the following case.

About two years ago, a physician brought his sister to me on account of hæmaturia and symptoms of cystitis. She had been delivered of a child a few months before, and the hæmaturia had occurred since then. On cystoscopic examination there was a distinct erosion surrounding the left uretral orifice, the rest of the bladder wall appeared healthy. I made an application of 10 per cent. solution of nitrate of silver to the erosion, and told the doctor that I feared his sister had renal tuberculosis, basing my fears on the statement of the authorities just quoted. The symptoms of cystitis promptly disappeared, there has been no recurrence of the hæmaturia, and the woman has been in good health ever since. The erosion in that instance was no doubt caused by the pressure of the head during delivery, and was not dependent upon any tuberculous affection. In women it is not uncommon to find patches of hyperæmia and even erosions about the uretral orifice, without any further significance than that they are evidences of a localized catarrhal cystitis. They disappear readily on a few direct applications of nitrate of silver solution.

The topical application of the silver salt solution has given me such uniformly good results in all other forms of cystitis, that when I meet with a case of cystitis that resists that treatment, I strongly suspect tuberculous cystitis.

Three cases in my series were suspected by me on the basis of that therapeutic test. Subsequent developments confirmed my suspicion. The advice has been given by the President of this Society, first to cure the tuberculous cystitis before taking steps to remove the diseased kidney. It would be rather difficult to follow this advice in the majority of cases, as the bladder would be constantly reinfected by the tainted urine. Further, it has been the experience of almost every operator that as soon as the diseased kidney is removed the bladder affection improves promptly, and in many instances disappears entirely, without further treatment. Of course, it must be admitted that every cystitis in tuberculosis of the kidney is not of a tuberculous nature. But whether the cystitis be tuberculous or not, it stands to reason that a cure of it can be more readily effected when the cause (the diseased kidney) is first removed.

As a rule, by the time that a diagnosis of renal tuberculosis has been made there is but little doubt as to which kidney is involved. Catheterization, therefore, to ascertain which kidney is affected, is seldom needed. But it is important to ascertain the functional capacity of the supposedly healthy kidney. Theoretically there is some risk attached to catheterization of the sound kidney in the presence of a complicating cystitis which may be due to secondary tuberculosis. But with Kelly's method, and the patient in the knee-chest posture, the risk is minimal in the hands of any one who is at all experienced with that kind of work. After the orifice is exposed, the end of the cystoscope may be so held as to surround it, then with a pledget of cotton soaked in an antiseptic, the interior of the cystoscope and mouth of the ureter may be cleansed. The catheter can now be inserted into the ureter without coming into contact with any other portion of the bladder wall than that which is within the lumen of the cystoscope.

Two of my patients had the sound kidney catheterized by me in accordance with the above technic, with no ill results following. Still, to avoid even this slight risk, a fair knowledge of the other kidney may be obtained by placing a catheter into the ureter of the diseased side, siphoning out the residual urine in the bladder, while the patient is still in the knee-chest posture, then placing the patient on her back, and whatever urine now collects in the bladder must come from the other kidney, as the catheter drains the urine from the diseased kidney. The urine from the supposed sound kidney should be examined both chemically and microscopically, and also subject to cryoscopy. The value of the last as a means of determining the functional capacity of the kidney is still *sub judica*. Kümmell, who, perhaps next to Israel, has had the largest experience in renal surgery, places great reliance in cryoscopy of the urine, and more especially in cryoscopy of the blood. In a personal communication to a friend, he stated that since he had been using these tests he had not lost a case of nephrectomy from inefficiency of the remaining kidney. Israel, on the other hand, looks upon the test as a plaything. From what I saw of the application of the test while in Berlin last autumn, I can readily understand that, unless it is carried out by an expert, it may prove very misleading.

In a case operated upon by me recently at Mount Sinai Hospital cryoscopy of the blood, carried out by one of the intestines, showed the freezing points of the blood, the so-called safety point. Still, the patient made a good recovery, the remaining kidney acting very efficiently.

A simple and fairly efficient test has recently been advocated by Völcker and Joseph[5] of Heidelberg. These authors have tried to overcome the objections attached to the dyes heretofore in use for the determining of the functional activity of the kidneys. They claim that they have succeeded in doing this by employing indigo-carmin in the following manner: indigo-carmin 0.4 gm. is freshly dissolved in 10 c.c. sterile physiological salt solution. Of this solution, 4 c.c. is injected deep into the glu-

teal muscles. The dye is sterilized by exposure to steam. They have never seen any inflammatory reaction or constitutional symptoms follow. Twenty minutes after the hypodermic injection is given, on cystoscopy blue urine can be seen coming from each ureter in rhythmical jets if the kidneys are healthy. The advantage of the indigo-carmin over the other dyes is that it does not readily mix with the urine in the bladder, and the stream from the ureter can be easily seen and followed to the most dependent part of the bladder, where it falls as a blue deposit. Its chief use, it appears to me, would be to ascertain beyond a doubt the existence of a second kidney, which, at least, is in a condition of functional activity. The authors express a hope that by further investigation they may be able to estimate the functional capacity of the supposedly healthy kidney by the intervals that elapse between the jets of urine as they are emitted from the uretral orifice. The method has been made use of by some of my confreres in Mt. Sinai Hospital, who have expressed themselves as being very highly pleased with it.*

Fortunately for us renal tuberculosis in women is in the vast majority of the cases limited to one kidney. Israel met with only two cases of bilateral disease in twenty-one cases. Another fortunate circumstance is the slow progress of the disease, so that the other kidney has ample time to gradually acquire the capacity of functionating for the entire economy. Suppression of function of the remaining kidney is a less frequent occurrence in nephrectomy for renal tuberculosis than in nephrectomy for most other renal affections.

When I was in Berlin last autumn I had the pleasure of seeing Israel, in his masterly way, remove several tuberculous kidneys. He told me that it is his practice now to remove the ureter in every case, for even when the ureter looks normal to the naked eye it may show evidence of disease under the microscope. He employs a second short incision parallel with Poupart's ligament for the removal of the ureter. As a rule, he closes the wound with sutures. He prefers to do this, he says, even with the knowledge that in the majority of cases the wound will break open afterwards. When the wound does break down, he finds that the healing is very much hastened by topical applications of the tincture of iodine. In one of my cases (Case IV) it was remarkable how quickly the sinus of over a year's standing closed with the biweekly aplications of this agent.

While the removal of the ureter with the kidney makes the operation more complete, and probably insures a better prognosis, it must not be forgotten that it was not until the past few years that Israel and other operators removed the ureter as a matter of routine. Nevertheless, some of the early cases operated upon are in the enjoyment of good health up to the present, a period of over twelve years in some of the cases. In my first case, operated upon over seven and a half years ago, with evident disease of the ureter, leading to a stricture in the pelvic portion, the ureter was not removed. The patient made a rapid recovery and has been absolutely free from any urinary or other symptoms ever since.

It is not necessary for me to enter into the technic of the operation for the removal of a tuberculous kidney any further than to say that the excision of the twelfth rib is of great aid in those cases in which the diseased kidney lies for the greater part above the border of the ribs, as it did in one of my cases (Case IV). When such a step is found necessary, the greatest care, however, must be exercised not to injure the pleura, which would be a much more serious accident than opening the peritoneal cavity.

Although I have been so fortunate as not to have had a death in my four cases,* I fully recognize that nephrectomy for renal tuberculosis carries with it a pretty high mortality rate in the hands of even the most skilled and experienced. Israel's operative mortality is 10.7 per cent., the lowest, as far as I know, of any operator's. Hunner's statistics of Kelly's operative cases had a mortality of 14 per cent. Morris had five deaths in eighteen nephrectomies (27.7 per cent.).

Israel has shown that a primary nephrectomy carries with it a lower mortality rate than when it is preceded by a nephrotomy. When, therefore, operative interference is indicated in renal tuberculosis, it is safer to remove the kidney at once, than to extemporize by first opening and draining the kidney. The ultimate prognosis of nephrectomy for renal tuberculosis in women is good. As already stated, some of the patients operated upon are in good health after the lapse of fourteen years. Of my own patients operated upon, seven, five, two, and one and a half years ago, respectively, all but one are in the enjoyment of excellent health. The exception occurs in Case II. This patient has developed a mild form of nephritis in the remaining kidney. The patient presents herself for observation every month. At the last two visits, the albumin had almost entirely disappeared, and the patient's general condition was very good.

Case I.—Nephrectomy for Stricture of the Right Ureter and Early Tuberculosis of the Right Kidney.[7] Mrs. L., aged 48 years, referred to me June 15, 1897. Had been under the care of Dr. M. Manges for six months for frequent micturition, pyuria, and pain in the right loin. Later, pain was most marked in the hypogastric and iliac regions. For three months she had apparently improved and gained in weight under general treatment and methylene blue given internally. Then the symptoms returned in greater severity. When seen by me on the above date, chief symptoms were frequent micturition, with some tenesmus and a feeling of discomfort at times amounting to a pain in the hypogastric region, and which frequently extended to the right loin. Latterly, she had lost some weight, but she was still fairly well nourished and had fairly good color. On bimanual examination the uterus was found small (menopaus had been established four years before); extending from the vaginal portion on the right side was a cord-like structure about the size of an ordinary lead pencil, running obliquely to the side of the pelvis. A cystoscopic examination after Kelly's method in the knee-chest posture, disclosed the orifice of the left ureter, apparently normal, emitting jets of clear urine from time to time; adjacent to it was a small area of redness and a bleeding point the size of a pin's head. The orifice of the right ureter was irregular in outline, swollen, and presented a nipple-like projection. Urine was seen oozing from it continuously rather than in jets. On attempting to pass a catheter into the right ureter it was found to meet with an obstruction about one inch from the bladder. A Kelly's ureteral sound met with an obstruction at the same site.

The patient was examined by my friend, Dr. Howard A. Kelly, who also found a stricture of the right ureter. Dr. Kelly stated that the diagnosis lay between calculous pyelitis and stricture of the

*I have recently made use of this method in a case of renal tuberculosis, operated upon with recovery. It proved to be very satisfactory and was not followed by any ill effects.

*Five cases now.

ureter. Dr. Manges and myself favored the diagnosis of a tuberculous lesion in the kidney with secondary ulceration of the ureter, especially as the patient's family history showed a taint of tuberculosis. There were absolutely no pulmonary symptoms, subjective or objective. The urine had been repeatedly examined by a competent man for tubercle bacilli, and always with negative results.

The right kidney was removed by me through a lumbar incision on October 22, 1896. It was firmly adherent to the perirenal fat. On its convex surface were scattered several miliary tubercles. On longitudinal section two small abscesses were found, one the size of a kidney bean in the cortex, immediately beneath the capsule; the other, the size of a split pea, in the apex of one of the pyramids. The pus from these abscesses showed tubercle bacilli in abundance. The patient made a rapid and satisfactory recovery, the entire wound being sutured excepting at its lower angle, where a small gauze drain had been inserted. The bladder symptoms promptly disappeared after the operation and the patient has enjoyed excellent health ever since.

Case II.—Nephrectomy for Ascending (?) Tuberculosis of the Left Kidney.[8] Mrs. S., aged 47 years, had been under my care for several months for what I diagnosed as tuberculosis of the bladder. Before coming to me she had suffered for over six years with painful and frequent micturition. So far as she knew she had never passed blood with her urine. A cystoscopic examination (Kelly's method) disclosed an elongated area of redness studded with small papules occupying the left upper quadrant of the bladder. The upper border of the area was situated some distance from the orifice of the left ureter. Tubercle bacilli, few in number, were found in the urine and in scrapings obtained from the surface of the affected area. When she came under my care the frequency of micturition during the day was very great, every half hour, and every fifteen minutes during the night. Under direct topical application, made twice weekly, the bladder symptoms improved considerably, so that the patient did not have to get up oftener than once an hour during the night, and during the day, while on her feet, she could easily retain her urine for three or four hours. The local condition underwent varying changes. The redness would at times almost disappear, as would also the papules, but fresh ones would appear from time to time.

After she had been under my observation for over a year (December, 1897, to January, 1899), it became evident that the fresh papules were taking a course in the direction toward the left uretral orifice, and I now noticed that the uretral orifice presented a nipple-like projection that I could not enter with sound or catheter, and that it did not emit jets of urine as it had formerly been doing. The right ureter was catheterized and the urine obtained from it showed on chemical and microscopical examination to be normal. Up to that time the patient had not complained of any pain in the region of the left kidney. I concluded, however, that the tuberculosis process had extended to the kidney and advised operative interference, to which the patient would not give her consent, owing to the absence of any subjective symptoms. On palpation the left kidney was found slightly enlarged and slightly tender on deep pressure. It was only two months later (March 3, 1899) that her consent was ultimately obtained, chiefly because she suffered from metrorrhagia, which caused her more alarm than the urinary symptoms. It is proper to state, however, that during the past two months her general health began to fail, and she had lost considerable flesh. At the operation the kidney was found extensively adherent to the fatty capsule and was situated pretty high up under the border of the ribs. The wound was closed with sutures, excepting a small space, where a small gauze drain passed down to the pedicle. The wound healed apparently by primary union and the patient was up and about at the end of the fourteenth day. Later, however, the lower angle of the wound opened, giving exit to a small quantity of pus, and the resulting fistula took about three months to close.

The excised kidney was slightly enlarged and was made up of a number of cavities filled with pus and caseous material. There was little or no healthy kidney substance to be seen with the naked eye. The contained pus showed tubercle bacilli in abundance. The patient's general health improved very much after the operation and she gained over thirty pounds in weight during the following year. Her bladder symptoms also underwent marked improvement and she could retain her urine for two or three hours at night. But during the past year her general health has not been so good, though she has not lost any flesh. She passes a sufficient quantity of urine, but it contains a moderate amount of albumin without any other abnormal impediments. There seems to be some relapse also of the bladder symptoms, as she has to get up every hour or two during the night, while during the day she can retain her urine three or four hours. A recent cystoscopic examination showed some old areas scattered over the bladder wall, but no papules.

I had reported this case originally as an instance of ascending renal tuberculosis in a woman, but more mature thought makes me doubt the correctness of that view. It is true that the clinical history and objective signs pointed very strongly to an ascending infection, but this is such a rare occurrence in woman that before a case is accepted as such the evidence should be unassailable.

Case III.—Mrs. A. L., aged 43 years, married 26 years, has 7 children, the last child born 9 years ago, no miscarriages. Menses regular until two months ago, since then every three weeks. Had always enjoyed fair health, until present illness, which began eight months ago, with frequent and painful micturition. Had been treated for cystitis for eight months prior to consulting me. When seen by me micturition was every hour and hour and a half during the day and about every two hours during the night. As far as she knew she had never passed any blood with her urine, nor did she have any pain in either loin. For the past few months the act of micturition was attended with considerable tenesmus, and she suffered almost constantly with pain over the hypogastrium. A distant relative had had pulmonary tuberculosis, otherwise family history negative. She was fairly well nourished, though moderately anæmic.

The right kidney lay below the border of the ribs and extended to near the umbilical line. It did not appear to be enlarged, was not markedly tender on deep pressure. The left kidney was not palpable. On cystoscopic examination (Kelly's method) the bladder was found to be very irritable and did not balloon out satisfactorily. Several small ulcerations were seen on the posterior wall of the bladder and a fairly good-sized ulcer near the apex of the bladder. The urine was acid, specific gravity 1005, moderate amount of albumin, a large quantity of pus, a few hyaline casts, a few red blood cells. No tubercle bacilli were found.

Direct topical application of solution of nitrate of silver (ten per cent.) were made to the affected areas twice weekly for four weeks. There was

some improvement in the frequency of micturition as a result of the treatment, but the pain and tenesmus persisted. She now entered as a private patient into Mr. Sinai Hospital, to be under more careful observation and to obtain the benefit from rest in bed.

On May 19, after being three weeks in the hospital, she began to suffer from some pain in the region of the right kidney and had slight rise of temperature (101° to 102° F. in the evening.) Although repeated examination of the urine showed no tubercle bacilli my suspicion of tuberculosis of the right kidney was being very much strengthened, particularly as the right kidney was markedly tender on pressure. Cystoscopic examination now showed the areas of ulceration to be about the same as at the first examination and that the right uretral orifice was very red and markedly swollen, and the catheter met with an obstruction about two inches from the bladder. The left uretral orifice was slightly reddened and apparently clear urine was seen coming from it in rhythmical jets. Under very careful precaution a catheter was passed into the left ureter and 6 c.c. urine drawn from the corresponding kidney. The urine had an acid reaction a specific gravity of 1014, urea 1.8 per cent., a mere trace of albumin, and a very few pus cells, with a small amount of blood, the latter evidently due to the catheterization.

May 30.—Nephrectomy. The fatty capsule was very intimately adherent to the convex border of the kidney and at one point a small abscess was found. It was with considerable difficulty that the kidney was enucleated from its bed of adhesions. The ureter was considerably thickened and dilated; I removed it down to the pelvic basin. The patient's condition did not seem to me to warrant a total extirpation of the ureter. The wound was closed in part, the remainder being left open for a strip of gauze to drain the bed of the kidney and another down to the pedicle of the ureter. The extirpated kidney showed several small abscesses in the cortex of the kidney, and an ulceration in one of the calyces. The report of Dr. F. S. Mandelbaum, the pathologist of the hospital, stated that the process was a tuberculous one.

The patient made a rapid recovery, the left kidney acting promptly and efficiently. The bladder symptoms underwent some improvement after the nephrectomy, but persisted in a minor degree for about six months afterwards, disappearing finally under weekly and bi-weekly direct topical applications of nitrate of silver (10 per cent.) and emulsion of iodoform (ten per cent.). An analysis of the urine May 15, 1903, nearly a year after the operation, gave the following results: Sp. gr. 1010, acid reaction, a faint trace of albumin, urea 1.1 per cent., few epithelial cells, and a few pus cells; no casts. The faint trace of albumin was doubtless due to the presence of epithelial and pus cells.

Case IV.—Nephrectomy and Excision of the Twelfth Rib for Tuberculosis of the Right Kidney. Miss S. S., aged 39 years, had hip joint disease in childhood, resulting in marked ankylosis of the left hip-joint, with considerable adduction of the thigh. For three years suffering from very severe cystitis, for which she had been an inmate in various city hospitals from time to time. Just before coming under my care in September, 1902, she had been an inmate of a prominent hospital in the city for several weeks, during which time the urine had been repeatedly examined and the diagnosis of intractable cystitis had been made. Tuberculosis had not been suspected in that hospital nor in any of the other hospitals where she had been treated for the past three years. She received very little relief from her stay in the hospital and was discharged as a case of incurable cystitis.

When she came under my care she was very anæmic and very much emaciated, weighing only 107 pounds, her normal weight being at least 130 pounds. Her expression was one of great suffering, she had to urinate every fifteen minutes during the day and at least every thirty minutes during the night. The act was attended with a burning sensation and was followed by severe tenesmus. She had a constant pain over the hypogastrium. It was only after a direct question that she confessed to having some pain in the right loin for a short time before consulting me. On palpating the right loin, the lower pole of the kidney could be felt just below the border of the ribs, but it was not tender on pressure. Owing to the deformity (the ankylosis) a satisfactory cystoscopic examination could not be made. What could be seen of the bladder wall presented a number of small areas suspicious of a tubercular process. She was subjected for a few weeks to direct topical applications of nitrate of silver to the bladder. Noting no improvement from the treatment, and the pain in the loin becoming more marked, I arrived at the conclusion that she was suffering from tuberculosis of the right kidney. I could just palpate the lower pole of the left kidney and could not detect any abnormality.

On October 24, 1902, I removed the right kidney. The usual oblique incision was made, and the lower pole of the kidney presented. It was normal to the sight and to the touch. The upper two-thirds of the kidney lay behind the ribs and on palpation was found to give distinct fluctuation. This portion of the kidney was very extensively and firmly adherent and it was not feasible to remove the kidney until the whole of the twelfth rib was excised. The abscess in the upper portion of the kidney was ruptured in the enucleation, and the thick, cheesy pus escaped in the wound. The ureter was not thickened, and any attempt at extirpating it was deemed unwise, considering the patient's condition and the difficult operation to which she had already been subjected. The greater portion of the wound was packed with iodoform gauze, only a few sutures being passed at the upper and lower angle of the wound. The patient rallied from the operation satisfactorily, and the remaining kidney responded promptly to the extra work thrown upon it. On the third day she was passing 50 ounces urine per diem.

The whole upper two-thirds of the removed kidney was occupied by several abscesses, there was scarcely any kidney tissue left. The pus from the abscesses contained numerous tubercle bacilli. The lower third of the kidney appeared perfectly normal to the naked eye. The upper part of the wound kept discharging grumous material for a long time and was unhealthy in appearance. The unhealthy granulations had to be repeatedly scraped away with a sharp spoon. She left the hospital about six weeks after the operation, with still a good-sized sinus. I lost sight of her then until December 30, 1903, a year later. I scarcely recognized her now, as she had improved so much in appearance. She had gained 23 pounds in weight, felt well in every respect, had absolutely no bladder symptoms, and was following her vocation as a domestic. She still had a small fistula at the upper angle of the wound dis-

charging thick, creamy pus. This healed very promptly under proper drainage and the application of tincture of iodine.

THE LYMPHOID AFFECTIONS OF THE UPPER AIR TRACT OF CHILDREN.

By WALTER F. CHAPPELL, M.D., M.R.C.S., ENG.

NEW YORK.

With great hesitation I consented to present this well-worn subject to this learned society of specialists. Your chairman, however, insisted that it would be of interest to you, viewed from the experience of a rhinologist and laryngologist.

A patient remarked, a few weeks ago, that it was strange to her that every physician of the present period examined the throat and nose. This is indicative of the progress which has been made during the past twenty years, in realizing the importance of a healthy mucosa in the upper air tract. No student was taught to make such examinations when I graduated, and beyond acute affections of the tonsils, nothing in this region was considered worth our attention. It is my belief, even at the present time, that we are only beginning to learn the part which the upper air tract plays as a highway of infection to the general system.

Of all the tissue in the upper air tract, none is so interesting and important as the lymphoid tissue, which we are to consider to-day. Affections involving this region may be classified as direct, or those embracing the lymphoid ring, and indirect, or those affecting the lymphatics adjacent to the upper air tract. The direct affections would embody diseases of the pharyngeal, tubal, faucial, lingual, and laryngeal tonsils, while the indirect would involve the cervical, mediastinal, and the bronchial glands. A brief statement as to their location is all that is necessary.

The pharyngeal, or so-called Luschka's tonsil, is familiar to all as regards location and normal function. It enters probably into the physiological act of deglutition more than into that of respiration, and is unimportant to us at this time, excepting when pathologically affected.

The tubal tonsils are lymphoid glands segregated around the mouths of the eustachian tubes, and serve no further purpose than that of keeping the entrance of these tubes moist, and thereby aiding the cilia upon their epithelial covering to wash away many infectious organisms that would otherwise enter the middle ear.

The faucial tonsils are familiar to all as to location, and their normal function, if any, is evidently one of aiding in deglutition, by moistening the bolus, the same as the pharyngeal tonsil. The formation of leucocytes, with more or less phagocytic action, is a particular function ascribed to the faucial tonsils. Their location needs no description.

The lingual tonsils are at the base of the tongue, and, when enlarged, encroach upon the superior surface of the epiglottis. No functionating properties have been assigned to them as yet.

The laryngeal tonsils are in the ventricles of the larynx, and aid in keeping the locality moist. The lymphatic glands connected with the respiratory tract are situated as indicated by their respective names, and their function one of diminishing the potency of any infection in the lymph passing through them.

I am actuated to this brevity relative to location and function by the consciousness of your familiarity with these details, and will make amends for the same in prolonging the discourse upon the affections of the structures.

Primarily, in the order of frequent involvement, is the pharyngeal tonsil. This small mass is subjected to no end of affections, as acute inflammation, chronic hypertrophy, acute and chronic follicular diseases, diphtheria, tuberculosis, and syphilis. It is still an unsolved problem as to whether the pharyngeal tonsil possesses the same phagocytic properties as the faucial tonsil, by which it exterminates partially the numerous cocci infections to which it is subjected. But this we do know, that it is more frequently the seat of inflammation in children, and that the various etiological factors producing inflammation in lymphoid tissue, may make their first attack here. Some of these, as sudden climatic changes, damp air, poor ventilation, irritating gases, poor nourishment, and stomachic derangement, although devoid of infectious qualities, are none the less productive of acute nasopharyngitis. This inflamed area offers fertile soil for the colonial production of infectious cocci.

Hyperplasia and increased connective tissue are not always the conditions found in this acute affection; but most likely it is a temporary turgescence which permits extreme changes in the dimension of the glands. Systemic derangements, anatomical formations, and individual temperament are factors bearing materially upon the diagnosis and symptoms of these acute inflammations. A great amount of hypertrophied tissue is easily recognized, but small masses or slight enlargements are usually overlooked. It is frequently noted that upon one examination the eye will detect and the finger palpate a large mass in the nasopharynx, and one worthy of operative interference, when at another examination there would scarcely be any mass present. This may be accounted for by the changed systemic condition, by the correction of the bowels, stomach, and vasomotor system. However, it is well to note here that during this temporary turgescence the child most frequently suffers with earache, breathes through the mouth, and affords symptoms of mental hebetude which characterizes this affection. Frequently all the usual symptoms are absent, while the more or less constant night cough, and intermittent nasal stoppage tells the tale.

These smaller growths are not so important in regard to their influence on general nutrition, as to their influence on aural conditions. Mild attacks of otitis media may recur for several consecutive winters, with summer omissions, or the night cough may be the only persistent symptom, and in either instance removal should be advised.

The relative degree of development or dimensions of the nasopharynx is an important factor in determining the danger line of the pharyngeal tonsil. Some children have ample space to accommodate a large mass of adenoid without serious derangement to breathing, and would thus offer a subject of controversy as to the advisability of removal. In the phlegmatic children of the clinics, but little

discomfort is manifested from the presence of large growths, which in a nervous, impressionable child would be the cause of great perturbation, but if found, even without symptoms, they should be removed, as they offer a field for infection.

An acute pharyngeal tonsilitis of a catarrhal nature is quite common in small children, without any other part of the lymphoid ring being affected. It is usually the result of a cold, and attacks the vertical clefts of the gland. The chief symptoms are high fever, the temperature rising to 105°, extreme prostration, and some enlargement and tenderness of the posterior cervical glands. I believe that any affection of the pharyngeal tonsil causes more systemic disturbance than similar affections of any other lymphoid tissue. Probably due to the almost direct communication between the lymphoid channels of the nasopharynx and the general lymphatic system. I recall one case where the infection penetrated the deeper tissues of the pharyngeal tonsil and formed an abscess sufficiently large to visibly push forward the soft palate. Occasionally an acute faucial follicular tonsilitis may be accompanied by follicular pharyngitis and naso-pharyngitis, each follicle being filled with the typical white plug.

The classical symptoms produced by adenoids are so familiar that I deem it only necessary to call your attention to those of audition. Acute suppurative otitis media and acute catarrhal otitis media are occasioned by the direct extension of the infection or inflammation of the pharyngeal tonsil to the middle ear. When the pharyngeal tonsil is enlarged from even systemic conditions, it impairs the hearing by direct mechanical obstruction of the Eustachian orifice, or by pressure upon the tube from the fossa of Rosenmuller. A continued pressure will eventuate in a catarrhal condition of the tube, and an infection will most likely produce an acute middle ear infection of the same character.

When from any cause there has been frequent or continued attacks of acute inflammation of the pharyngeal tonsil, there is, as a sequel, an increase in the amount of lymphoid tissue, likewise connective tissue and fibrous stroma. This may produce a soft or a hard mass, and for practical purpose differentiates the two kinds of adenoids found, viz., soft and hard. This condition respects no race and regards no clime. It appears with equal frequency behind the door of the cottage and the palace gate, and alike in infants fed upon carefully pasteurized milk, and those deriving their sustenance from a healthy natural source. Whereas, not a distinctive disease of infancy, yet it has been found in cases of two months old babies, and claimed by some to be actually congenital. Some authors claim that this condition results from a natural progressive hyperplasia, and discountenances the various infections and inflammatory factors which precede it.

Whether as a sequel, or as a port of infection for the exanthemata, we do not know, but that we find an increase of lymphoid tissue after these diseases cannot be denied. More definite conclusions can be formed after it has been definitely proven that the exanthemata are of bacterial origin. We know that chronic hyperplasia of any lymphoid structure predisposes to the infection of tubercle bacilli, streptococci, diphtheria bacilli, and pneumococci; then why should it not obtain as well in all diseases of bacterial nature, offering, as they do, such an easy entrance for infectious organisms?

Several cases of diphtheritic infection of the pharyngeal tonsils alone have come to my notice. They were all accompanied by great prostration and high temperature. I have never seen any syphilitic manifestations in the nasopharynx of children.

One case of primary tuberculosis of the nasopharynx has occurred in my practice. A young girl who had recently been operated upon for adenoids, had tuberculous symptoms, beginning a few weeks after the adenotomy, with every evidence of an acute process. This infection soon spread down the side of the tongue to the larynx, and subsequently involved the lungs. The infection probably resulted from sleeping in a room long occupied by a sister who had recently died of tuberculosis. Whereas, it is exceedingly difficult to find the tubercle bacillus or even giant cells in adenoid masses; yet it is of serious import when we learn that of thirty-five guinea pigs inoculated with extirpated adenoids, seven died of tuberculosis (Dieulafoy).

There are some conditions obtaining in children which offer similar symptoms to those of adenoids, which I have given in a former paper, but I deem them of sufficient importance to bear repetition here: (1) Lymphatism; (2) syphilitic and gonorrhæal rhinitis; (3) congenital occlusion of the nares; (4) digestive disturbances; (5) congenitally high-arched palate; (6) small or occluded nostril; (7) unusually small postnasal space; (8) anterior projection of the bodies of the cervical vertebræ; (9) some malformations of the soft palate; and (10) hypertrophy of the tongue.

In view of the conditions simulating adenoids, it is unwise to give a positive diagnosis without the direct proof of digital or pharyngoscopic examination. There is considerable lymphoid tissue in the lateral pharyngeal folds, and any acute process attacking it will produce symptoms out of all proportion to the local appearance. This is likewise probably due to the direct relation of the lymphatics with the general lymphatic system. A few small, yellow plugs on the lateral folds of the pharynx, with very little redness, may be all that is visible in the interior of the throat, whereas the posterior chain of cervical glands may be enormously enlarged and massed together in a continuous ridge, which may be red and tender, and give evidence of a threatened suppuration.

Many such cases have come to my attention this spring. In some there was very little evidence showing the point of infection; again, others had a varying degree of follicular pharyngitis lateralis. In all the external glandular affection was very marked. In one case the pharyngeal wall and the surface of the tonsil was covered with numerous small, superficial abscesses, not exceeding a pin's head in size. The cervical glands were involved, both anterior and posterior, to the sternomastoid, and numerous other small glands as low as the clavicle. Three of these suppurated. On opening the superficial abscess already described, a small quantity of yellow secretion was pressed out, which, on examination, was found to contain numerous streptococci and a few staphylococci. In all these cases of infection through the posterior lateral pharyngeal wall, the secretions were found to contain streptococci. I do not believe that sufficient attention is paid to the mucous membrane of this region, as in my experience it is very susceptible to all those forms of infection which produce marked systemic toxæmia.

We might properly take up at this point a brief consideration of retropharyngeal abscess, which is somewhat distinctive of childhood, although found frequently in adults. The locus of infection may be in the nasopharynx, oropharynx, or laryngopharynx, likewise in the median line or to one side. Formerly it was considered a result of carious vertebræ, and to occur only in those of scrofulous or syphilitic taint. However, recent investigations have

shown that in children few cases result from carious vertebræ, and that syphilis probably only predisposes to the condition.

Anatomically considered, there is a space anterior to the aponeurosis covering the bodies of the cervical vertebræ, and covered in front by a sheath of connective tissues. This is limited above by the base of the cranium, and extends below to the mediastinum. In this space are found numerous lymph nodes, which are directly connected with the lymph channels from the pharynx, nasopharynx, and neck. In view of this direct lymphatic connection, any infectious conditions obtaining in any of these localities would tend to throw certain of the germs characterizing the infection into these nodes. In this way we have retropharyngeal abscesses resulting by metastasis from cervical adenitis, tonsillar abscesses, suppurating otitis media, and in one case reported (Leebert's) the cause was said to be an antral empyema. The exanthemata in children are frequently mentioned as a cause, which is one more proof, apparently, that they are of microbic nature. Infection from a foreign body, impaired nutrition, erysipelas, and acute inflammatory conditions of the lymphoid structures of the pharynx, are all etiological factors. I would particularly call your attention to the "grippe" bacillus as a causative factor in many cases. Tuberculosis, however, may play an important part, and once more it is reasonable to suppose that the bacillus travels through the pharyngeal tonsil, or lateral walls of the pharynx, as portals of entrance, to the less resisting lymph nodes of the retropharyngeal region. The farther the tubercle bacillus gets away from the port of entry the more virulent it becomes. This obtains as well in inspired air as in ingested foods. This virulence is probably not due to more activity on the part of the bacillus, but to the diminishing resistance on the part of the structure encountered. A bacillus will pass through a faucial tonsil and infect a cervical gland, and through a pharyngeal tonsil and infect a retropharyngeal lymph node.

In the 204 cases analyzed by Bokai, 189 were idiopathic, seven were due to carious vertebræ, seven were due to burrowing of pus from an abscess in the neck, and one was due to traumatism.

Retropharyngeal lymphadenitis may occur at an extremely early age; Bokai reports one case occurring in an infant eight months old, and in this case such severe symptoms of suffocation arose that tracheaotomy was necessitated. Casselberry likewise reports a case in an infant four months old, in whom the infection was probably the result of pseudomembranous tonsillitis of infectious nature. I have also had a case occurring at the early age of five months.

The symptoms vary somewhat with the location of the disease. If in the nasopharynx, the child breathes loudly and with the mouth wide open, but is not so subject to choking spells as when the disease is in the oropharynx. The difficulty of respiration, as well of deglutition, is materially increased the lower down the tumor is situated. These conditions sometimes go undetected for a long period, and the difficult breathing, indisposition to take nourishment, loss of weight, and general fretfulness of the child, are attributed to causes remote to that existing. A systematic examination of the entire upper respiratory tract with every aid at command should enable one to find the cause of the trouble. Not alone the eye, but also the finger and probe, should be called into action. The tumor in tuberculous and scrofulous children will offer but little redness to attract the eye, and the bulging may be so slight that it, too, escapes observation, hence the importance of using the finger to investigate the pharyngeal wall as far up and down as is practicable.

No condition yields so delightfully to surgical interference as this, if properly treated. If allowed to continue undisturbed, it may burrow down and reach the mediastinum, or break out into the cervical tissues, and gravitate through the layers of fascia into the pleural cavity. Ingalls recites a case having a sinus of ten inches, remaining after opening the abscess.

The faucial tonsils offer easier opportunities for abstract investigation than any of the other tissues of the lymphoid ring, because of their situation under direct observation. In their normal state they are but small masses of lymphoid tissue upon a cushion of areolar connective tissue. Their primary function is to manufacture mononuclear leucocytes for the destruction of the one hundred varieties of microorganisms constituting the flora of the human mouth; secondly, they filter out the pathogenic organisms contained in the inspired air and ingested food which pass over their surface, and thirdly, they furnish a small amount of mucus to facilitate the act of deglutition.

Hypertrophied tonsils may be divided for description into (1) Hard or fibrous tonsil; (2) The soft or adenoid variety, which is the one more frequently apparent in children.

Knight offers a further division for clinical consideration into (1) Those whose size interfered with deglutition or respiration; (2) Flat tonsils, not especially enlarged, but prone to recurrent attacks of inflammation, and occasionally the foci of suppurative inflammation; (3) A class of tonsils in which there may be little apparent encroachment upon the pharyngeal space.

Whereas the tonsils in children are subjected to all the diseases which obtain in the adult, simple hypertrophy is the one coming most frequently under observation. The line of demarcation between the harmful enlargement and the unharmful depends upon the judgment of the physician and the idiosyncrasy of the patient. Some children will tolerate enormously hypertrophied tonsils without evincing any of the annoying symptoms which a very slight enlargement will produce in others. The size should not be our only factor in determining a diseased tonsil, for a hypertrophy can readily be seen under most circumstances, but a large tonsil may escape the attention of persons with considerable experience; by this I mean the so-called buried tonsil, which lies hidden between the lateral pharyngeal wall behind, and the opercular fold in front, and which extends high up in the lateral pharyngeal vault. It is sometimes a more dangerous condition than the marked hypertrophy of the gland which occupies a large part of the pharyngeal space. On examining the throat we may find only a small part of the tonsil exposed, but the anterior surface of the soft palate presents a round, bulging appearance, and on palpation the tonsillar mass can be felt through the palatal walls.

These encapsulated tonsils are subject to all the disease of a free tonsil, but the symptoms are all more pronounced. A paretic influence on the soft palate and a protrusion backward into the nasopharynx produce symptoms similar to postnasal adenoids. A case once came under my observation in which the nasopharynx had been curetted twice for adenoids without any abatement of the symptoms; after considerable controversy, I removed the buried tonsil and all the symptoms disappeared. In two children, aged respectively 10 and 11 years, under my care, there existed more or less constant

nausea extending over a period of two years; after the removal of the encapsulated tonsils there was immediate relief. One tonsil only had been removed in both cases, the remaining tonsil was considered too small to cause any trouble. In these cases of buried tonsils a peritonsillar abscess is not uncommon, and in some instances when lymphoid tissue is abundant the tonsil extends downward along the side of the pharynx to the epiglottis. In a patient aged six years one of these faucial tonsils became infected and progressed to suppuration, the abscess burrowed down as far as the epiglottis, and pressing backward produced urgent symptoms of suffocation.

Again, a large, flat, mushy tonsil, with wide open crypts, and but little fibrous stroma, offers a far more fertile locus of infection than the smooth, hard, round hypertrophy, which causes the two tonsils nearly to meet in the medium line.

Some of the causes inducing hypertrophy are sudden changes in temperature, direct irritation from gases and ingesta, scrofulosis, direct infection from the innumerable cocci passing over the surface, inherent rheumatic diathesis, and, indirectly, bad gastroenteric conditions. the subjective symptoms are occasionally pain and acute inflammation, but most frequently a sense of discomfort only as of a foreign body in the throat, with a frequent desire to swallow; regurgitations of fluids through the nose, if the tonsils are very large; and gastric disturbances and vomiting, which are recited by some authorities as reflex neuroses, but they may well be the result of mechanical irritation to the fauces.

As a station for the deposit of morbific germs, the tonsil stands before any organ of the body. It is subjected to direct local infection from food, liquid, and air. Its projecting body and open-mouthed crypts are peculiar factors for stopping all organisms intended either for lung or alimentary canal, and though possessed of characteristic protective qualities in the phagocytic action of its leucocytes, the immense forces brought against its barrier must needs force it to succumb in many instances. Some author has offered as argument against the removal of the tonsils, this same protective agency which it embodies, and adds that nature has protected the human body against the invasion of germs by placing those great lymphatic guardians over the entrances thereto. Moreover, he claims that infancy and childhood are protected by larger masses of lymphoid tissue than adult age, because of the lack of discrimination in the infant of that which is pure to breathe or proper to eat. However beautiful this is in theory, in fact we find systemic infection in children more frequent than in adults, resulting most probably from infection through the tonsil. Though we find the tonsillar tissue itself infrequently the seat of tubercle infection (only 5 per cent. in 1,000 specimens of tonsils and adenoids examined), yet we find the adjacent cervical glands, which are the lymphatic reservoirs of the tonsils, infected with tuberculosis in an alarming percentage of cases of tuberculosis. Although the crypts and lacunæ of the tonsil offer every favorable feature for the collection and cultivation of the tubercle bacillus, yet we find latent primary tuberculosis of the tonsil comparatively rare. Pluder and Fischer demonstrated the presence of tubercle bacilli in the tonsil limited to the mucosa, in five out of thirty-two cases examined; Lermoyez, in two of thirty-two cases; Gottstein, in four of thirty-three cases; Brindel, in eight of sixty-four cases (*Archives of Rhinology and Larynology,* 1896). Jonathan Wright (*Medical News,* January 19, 1901), has this to say in regard to this channel as a means of systemic infection: "The mucous membranes absorb, the lymphoid material harbors, and the lymph channels carry the tubercle bacillus, and yet are themselves relatively immune to its morbific influences as compared to the walls of the bronchioles and air vesicles." The frequency of so-called scrofulosis associated with hypertrophied tonsils may illustrate the relative immunity of tonsillar tissue to tuberculosis itself, and likewise demonstrate that the infection has been passed on to the next of nature's protective agents, the lymphatic glands. The frequency of scrofulosis in certain sections of the country where poor milk is furnished by "scrub" cattle, which are probably tuberculous, may in a measure be accounted for by this same filtering process of the tonsil, the projecting mass with wide crypts straining out the bacilli from the ingested milk, which then pass through to the lymphatics, where they establish themselves.

There is a fossa above the tonsil called the supratonsillar fossa, which by many is deemed a large crypt, but in reality is a blind pouch, offering the peculiarly favorable features of darkness, warmth, and moisture to the processes of germination. Here collect vast quantities of streptococci, staphylococci, pneumococci, tubercle bacilli, and Klebs-Loefler bacilli, all of which await a favorable diminution in the resistance of the tonsil to invade its inner body and deplete its vitality. It is reasonable to suppose that from this pouch more tonsillar abscesses and quinsy sore throats result than from any of the other loci of infection. Here are deposited food products, which in time decompose, producing toxins which easily invade the tonsil, and pass into the general system, occasioning toxæmia. Unquestionably many of the febrile conditions in children may be accounted for in this manner.

Affections of the lingual tonsils in children are comparatively infrequent, and while these may be sympathetically as well as directly involved, yet their diseases are by no means of such import as in the adult. Lenox Brown has probably devoted more study to the diseases of the lingual tonsils than any other observer, and from his investigations one finds slight apprehension of involvement in the child. Their situation offers equal opportunity for infection from ingested material as the faucial tonsil; but not so favorable for inhaled infection, as the epiglottis covers in part their outer surface during inspiration.

Another probable factor aiding their immunity is the presence of ciliated epithelia even in the crypts of the lacunæ, which would tend to wash away infected material from these bacterial repositories.

Digestive derangements, colds, inherited rheumatic diathesis, and bacterial infection are etiological factors producing affections in this locality. The three first mentioned causes produce only turgescence of these lymphoid masses, which may be unilateral or bilateral. Enlargement of this character has occurred in several cases in which serious disturbance to respiration resulted, and in one case reported by Hickman (*Transactions of the Pathological Society of London,* Vol. XX.), death from asphyxia resulted a few hours after birth, and the autopsy showed an "enormous hypertrophy of the normal tissue of the posterior portion of the tongue, the anterior being unaffected." However, the majority of observers have claimed the liability of this affection begins only at fifteen or sixteen years, and continues to the age of seventy.

It is believed by Swain that there is some connection between hypertrophy of these glands and infectious diseases, as in many post-mortem examinations observed by him after typhoid fever, scarlet fever,

measles, and diphtheria, hypertrophy has been found. It has also been noted in anthrax and tuberculosis (Lenox Brown, page 396).

In some phlegmonous conditions of either the pharyngeal or faucial tonsil, we find a similar, though somewhat modified condition in the lingual tonsil, and particularly does this obtain in cases of retropharyngeal abscesses. In scarlet fever, when the faucial tonsils are greatly infected, producing the infiltration of surrounding tissue, which we have all learned to fear, the lingual tonsils may also be implicated to a similar degree. The symptoms become very alarming as the pressure of these infiltrated masses upon the epiglottis, together with their weight, drags the tongue backward over the larynx and produces symptoms of suffocation. In milder cases these symptoms are absent while the subject is sitting up, but on his lying down the symptoms of suffocating appear.

In one case under my care, an abscess formed at the base of the tongue on the right side, and nearly proved fatal. In several cases I have been obliged to have the tongue held forward by relays of assistants for two days. It does not seem that the possible affections of the lingual tonsils in children are fully appreciated.

There is no remedy for internal administration, nor any local application, of special use in the acute affections of these tissues. The simple affections are usually self-limited, while those of a specific nature have a well recognized treatment, with which you are all familiar. It is important, of course, always to observe cleanliness and employ some antiseptic applications. Internally I have found the best results from the use of a Guaicol of quinine. If the glands connected with the lymphoid tissue of the upper air tract become affected, an application of ichthyol and ice externally is beneficial, but it must be continuous.

The more or less chronic affections of this region should not be temporized with, and the best results may be expected from surgical measures. This applies more particularly to the lymphoid tissue in the nasopharynx, for there is seldom sufficient tissue at the base of the tongue to warrant its removal.

I do not mean to be understood as advocating the removal of small pieces of adenoids and small tonsils which are not causing any symptoms. In such cases suitable climate and proper attention to the stomach and intestinal canal will assist in taking care of this tissue, but large tonsils and large lymphoid masses in the nasopharynx should be removed, even if they do not produce symptoms. We have always to remember what a source of infection they may be the moment they are attacked by any contagious disease.

A small quantity of adenoid tissue in the nasopharynx, if it produces cough, frequent colds, earache, or any other symptom, should be removed.

Having determined that the adenoids or tonsils, or both, should be removed, there are many things which a specialist should consider. The child's condition should be carefully looked into, and if he has recently recovered from any contagious disease, or ear trouble, or has had a slight cold or bronchitis, the operation should be deferred. The urine should be examined, and the temperature taken, as in several instances under my care albumin in the urine and a rise in temperature have been forerunners of scarlet fever.

If there is a history of rectal temperature not exceeding 101°, and extending over a week or ten days, I do not consider it as a contraindication. Subacute tonsillitis, or pharyngitis, readily accounts for such a temperature. Of course the operation may be done, if necessary, at any season of the year, but if we can elect a time, I consider May and June preferable months; at this season a child is kept in the house a minimum length of time, and has the entire summer for a complete restoration of the circulation of the upper air-tract, and a consequent cessation of all the symptoms.

Having decided on the operation, I send a list of the things required, and select an early morning hour, usually before eight o'clock. This gives us the child with an empty stomach, avoids the irritation and fretfulness caused by keeping away the breakfast, and, furthermore, it gives the child the entire day to recover from the operation, and when evening arrives it is usually in a favorable condition for a quiet night. In a few instances, in which the tonsils are free and there is only a small adenoid, I find it feasible to remove them without an anæsthetic, but I usually do not advise this procedure; and as a choice of anæsthetics, in a child over three years of age I prefer gas and ether, or ether and ethyl chloride. In a child under three years, with a skilled anæsthetist, I am satisfied to begin with a few drops of chloroform, and then run into ether. Chloroform alone I consider very unsafe.

The anæsthetic should be given in a room other than the one selected for the operation, and the child brought in and placed on the table when unconscious. Of course, any table will do for such an operation, but in order to facilitate matters, and to have everything as perfect as possible, I employ a table of my own device, which I have already described in a previous paper. The points of convenience in this table are that it can be carried in a bag to the patient's house, and occupies a small space close to the window. It is high and narrow, so that it brings the patient within easy reach, and has a movable extension, which may be lowered or elevated as required.

The patient being under the anæsthetic, with the mouth gag in place, I introduce my finger into the nasopharynx and examine the location and condition of the lymphoid tissue. I then examine the tonsils, and if there are any adhesions, separate them with the tonsil hook, and quickly remove both tonsils. If the child is in the sitting posture, which I usually prefer, its head is bent quickly forward, allowing the blood to drain out of the mouth. A moment later, my assistant wipes out the pharynx with an antiseptic wipe, and the curette is passed into the nasopharynx, and with two or three quick sweeps the adenoid tissue is removed. The patient is again held forward, so as to drain away the blood. Most of the lymphoid tissue comes out with the curette or the blood, as it drains from the mouth. A moment later the finger is introduced to make sure that all the adenoids have been removed. If this has been complete, the patient is replaced to a recumbent posture and turned well over on the side to favor drainage. At this stage a towel is dipped in ice water and quickly put over the face, which immediately flushes, and the bleeding ceases almost immediately. Two applications of the iced towel will certainly control any ordinary hemorrhage.

Before removing the patient from the table, I look into the throat to ascertain that everything is all right, and that there are no tags of adenoids hanging from the nasopharynx. In an ordinary case, with everything in readiness, and with no complications, the operation should not require more than two minutes.

If either tonsil is buried, or there is a great amount of adenoid tissue, the time required for removal would be a little longer, and the administration of more ether required. In these cases, after the tonsils are removed, I wipe out the pharynx, and apply ice-

water to the face to control the hemorrhage, and then continue the anæsthetic.

After the child is placed in bed on its side, I expect the anæsthesist to remain until the child vomits, which it usually does within ten or fifteen minutes. I then consider it safe to leave the patient, with instructions to the nurse to keep it absolutely quiet, and darken the room, so as to encourage sleep. The following printed rules are also left with the nurse:

First Day—

1st. Keep quiet in bed on the side, and take the temperature by rectum twice a day.
2nd. No gargles or nasal sprays.
3rd. If restless or in pain give —— drops of paregoric.
4th. Nothing hot to eat or drink. Give only cold milk, ice-cream, cold broths, or soups.
5th. Give customary medicine for moving bowels.
6th. If much bleeding, telephone to the doctor, and apply iced towels at intervals of two minutes to the face.

Second Day—

1st. Keep quiet in bed.
2nd. Small quantities of warm food may be given at regular intervals.

Third Day—

1st. Slight exercise indoors.
2nd. Any light food patient wishes.
3rd. Use antiseptic gargle.

Take the patient to see the doctor two weeks after the operation.

The directions are left in this way, as otherwise they are often forgotten, and the attendants do not know what to do in case of an emergency. In infants, and in children under two years of age, I employ a small tongue depressor and gag, as the ones in ordinary use take up so much room in the mouth that they retard the quickness of the operation. A small curette is also advised, as the usual size for older children is likely to do damage to the nasopharynx.

Preferably I use a Matthews tonsillotome, as it pulls out the tonsil, and is less likely to injure the pillars of the fauces, which is a frequent cause of profuse hemorrhage. If the tonsils are very soft, and full of long furrows, the forks of a Matthews tonsillotome pull out, and in these cases a McKenzie instrument, or a modification of it, is preferable.

Accidents Which May Occur During the Operation.—The pillars of the tonsil or its cushion may be severely injured by an assistant pressing too hard externally on the tonsil. If I employ pressure at all, I do it myself, so as to have it completely under control. In operating with a curette, or forceps, in the nasopharynx, the septum or Eustachian prominence may be wounded, or an unnecessary amount of mucous membrane may be stripped off the posterior pharyngeal wall. The septum and the Eustachian prominences are more likely to be injured with the forceps, the posterior pharyngeal wall with the curette. It is very important, in using the latter, that the pressure be lessened as the sweep presses downwards.

One patient came to my clinic the day after the tonsils and adenoids had been removed at another hospital, and I found the soft palate completely ruptured from its free margin to the edge of the hard palate. This case gave a history of congenital syphilis, and from experiments I have made, I do not think that any ordinary force could rupture the palate of a healthy child. It is very easy, however, to pinch off the uvula or bruise the soft palate with the forceps.

Sequelæ.—Personally, in an experience of twenty years, I have never had an alarming hemorrhage during the operation, nor secondary hemorrhage. Such an occurrence may usually be avoided if a careful history of the child is taken, and its condition fully considered.

Too vigorous operative procedures should also be avoided, and the postoperative directions should be fully carried out. I cannot condemn too forcibly the belief of some operators that details are unnecessary in such a minor operation. Of course, we may go on for years without an accident, but when it does occur from want of proper care we are not likely soon to forget it.

Two cases of otitis media have occurred in my practice, a single ear was involved in one instance, but both in the other, without any assignable cause. In another patient the temperature rose to 105° four days after the operation, and remained there for nearly a week, when a central pneumonia appeared. In still another case, albumin and casts appeared in the urine after the operation, and continued for three months, but I have no doubt this would have occurred had the child taken ether for any operation.

Scarlet fever developed in one patient two days after the operation, and measles in two cases five days after the operation; this occurrence, however, should not, in my opinion, be connected with the operation.

7 East Fifty-fifth Street.

A CLINICAL OBSERVATION OF ONE HUNDRED AND SIXTEEN CASES OF TYPHOID FEVER, WITH SPECIAL REFERENCE TO THERAPEUTIC FASTING.

By R. M. HARBIN, M.D.,
Rome, Ga.
Member of the Georgia State Board of Health.

During the recent New Orleans session of the American Medical Association before the section of Practice of Medicine, it was my privilege to present a report of treatment of ninety cases of typhoid fever, with special reference to therapeutic fasting[1], and since then twenty-six cases have been observed, which have encouraged me to emphasize more than ever certain conclusions drawn from a study of the dietectics of this disease.

The clinician and bacteriologist have been working out certain problems from different points of view, in typhoid fever, and it is gratifying that their results have been reciprocally confirmed in a great measure, and from a standpoint of the former the results of these incomplete studies are offered:

While bacteriology has furnished many unsolved problems concerning the nature and manner of production of toxin of the bacillus typhosus, in many of these experimental studies some conclusions have been formed that coincide with clinical facts. The difficulty of filtering away the toxin in solution from the bacillus typhosus has rendered its properties less well understood; but we are warranted in concluding that the toxin is probably produced by bacterial disintegration, and takes place more rapidly in the human organism than in culture media.[2] As this bacillus is found by far more frequently in the feces, we look for the greater source of the toxin production in the intestinal canal, where the pathognomonic lesions of the disease occur. The bacilli found in the feces represent only those that have escaped absorption, which are probably a very small per cent. of those actually existing in the digestive tract. These deductions have an important bearing on cer-

tain clinical observations that have been made since the disease was first studied:

In the first place, there is a greater amount of toxemia in cases associated with gastro-intestinal disturbances, which is not dissimilar to the manifestations of diphtheria, in which the toxemia is proportionate to the amount of local disturbance of the pharnyx. Cases attended with diarrhœa usually have a greater degree of toxemia, and where the reverse condition obtains, the amount of bacterial production is greatly reduced. Emaciation occurs independently of the amount of food taken into the stomach,[3] and this is suggestive of the fact that but little food is assimilated, and the remainder furnishes a good culture medium for the bacilli, thus producing a greater amount of toxemia. The fact that robust individuals are more susceptible to the disease, and usually produce the more violent types, can hardly be accounted for by any rationale, except, possibly, they consume more infection. As in other infectious diseases different individuals are affected differently by the specific toxin. Robust young adults seem to be more susceptible to the effects of the toxin of the bacillus typhosus, while extremes of ages and the anæmic are less so.

The specific toxin produces pathognomonic symptoms of typhoid fever, and is not necessarily attended by high temperatures. Where there is hyperpyrexia without typhoid symptoms, there is a probability of mixed infections. These facts lead us to conclude that the dietetics furnishes the most important field of therapy, and a restricted diet and fasting are the rational indications in the treatment of these severe cases, and the dangers from inanition are by far less than those from toxæmia.

Etiology. For practical purposes typhoid fever may be assumed to be water-borne in sporadic cases, but where cases occur secondarily there is a probability of indirect infection by other means.

Some observer[4] has recently said there are only six authentic instances where the bacillus typhosus has been discovered in drinking water, but the epidemiologic evidences prove the reverse. Well-water is a fruitful source of infection, because of the exclusion of sunlight and air. Experiments have proved that 98 per cent. of the bacilli are killed by a two hours' exposure to the sun's rays. In this report ninety-six cases drank well, while twenty drank hydrant water, and the greater proportion of population, where this observation was made, is dependent on hydrant water for drinking purposes. The variation of types of the disease is more due to individual conditions rather than types of epidemics.

Typhoid fever is a disease of early adult life, and the youngest herein reported was two and the oldest sixty; an average 20.3 years old. There were sixty-four males and fifty-two females. These observations indicate that the disease is less frequent in the colored race as census reports.

Diagnosis: Dr. Osler's suggestion was adopted in the diagnosis of these cases, viz., any continued fever lasting beyond a week, without obvious cause, and resisting the effects of quinine, may be assumed to be typhoid. All doubtful cases, except tuberculosis, should be assumed to be typhoid, until proven to be otherwise.

The Widal reaction is the greatest achievement in the diagnosis of typhoid fever, but we are necessarily dependent on clinical diagnoses during the first week, at the end of which time the reaction is shown in only 6 per cent. of cases, while on the thirtieth day the per cent. of reaction is 92.[5]

Prognosis: Nothing is more uncertain than the ultimate result of a case of typhoid fever, and statistics, in my opinion, would show almost as many deaths among those cases classed as mild as in the severe ones.

In this report there were 79 classed as mild, in which two deaths, or 2.5 per cent., occurred; while there occurred a mortality of two, or 5.4 per cent., in 37 cases classed severe. This may be due to the fact that the former are not subjected to such rigid surveillance as the latter. Hemorrhage and perforation occur quite as frequently in the mild cases. "Walking cases" furnish a great danger, and I have seen a fatal hemorrhage where the diagnosis was only made after the accident. The younger the case, the milder will be the disease. If the onset is sudden and severe the duration will be shorter. The degree of pyrexia is not necessarily an index of gravity. Pulse frequency, barring individual peculilarities, is a measure of danger. Constipation is a more favorable symptom than diarrhœa. Persistent tympanites is a most unfavorable smyptom, because of increased area for absorption, and favors the production of hemorrhage and perforation. Delirium, when due to hyperpyrexia, is not as bad significance as that occurring with a low temperature.

Treatment: In the cure of typhoid fever there are no specific remedies, and in our search for such we often fail to utilize certain accepted principles in the management of this disease. I am convinced, from personal experience, that it requires a more acute observation to decide the suitableness of any plan of dietetics than it does to discern the physiological effects of drugs, and for this reason the food question is not properly appreciated. There is a prevailing sentiment among clinicians to use less drugs, at the same time not denying their value to relieve certain symptoms and complications.

The merits of hydrotherapy are established beyond peradventure, but in the dietetic management observers disagree. Some observers[6] have recently advocated a more liberal diet, but that is *sub judice*. It is safe to say that a great majority of clinicians of long experience still feed typhoid patients in a very restricted manner.[7] There are obvious physiologic reasons favoring the latter procedure. The text-books usually close the subject of treatment by a few remarks on food, which should be first discussed in detail. The proper food management of a typhoid case will well nigh shield him from every danger incident to the course of the disease, for there exists no greater danger than to have undigested food in the intestinal canal, which means a greater degre of toxemia. Cases attended by diarrhœa and tympanites, hemorrhage, perforation, hyperpyrexia, and asthenia furnish the greater dangers which are aggravated by deranged gastro-intestinal functions. It is a common observation that those patients who are fed more liberally show more marked emaciation. The eliminative treatment, so-called, has no place in the rational treatment of typhoid fever, except to mitigate the sins of overfeeding, as increase of peristalsis favors the absorption of toxin. Sthenic cases usually furnish the more dangerous types of the disease, which are marked by high temperatures and considerable gastrointestinal derangements, which exhaust the patient by far more rapidly than the withdrawal of food would do.

It is in this class of cases that therapeutic fasting has served me so well in the management of this series of cases. It is noticeable that there is less emaciation, with the same degree of fever, in typhoid fever than in any other acute fever, and what the patient loses in food is more than compensated by a lessened amount of toxæmia.

Death from starvation occurs ordinarily in eight days after the withdrawal of all food and water.

The same result occurs, even though dry food is allowed, but life is prolonged forty days when water is freely given.

Physiologists have demonstrated, by experiment on animals, that nitrogenized food and water are essential to a normal metabolism, and that carbohydrates are nonessential, as there is ample storage of this class of food in the organism.[8] This would lead us to infer that there is little necessity for carbohydrate food in a sthenic case of typhoid fever, lasting a few weeks, and it is only necessary to maintain a nitrogen equilibrium.

The pathological anatomy of typhoid fever shows a condition of gastrointestinal catarrh with hyperplasia, with a great reduction of all the digestive fluids. Saliva is diminished, and hydrochloric acid is usually absent in the gastric juice, and, in fact, almost every condition unfavorable to digestion exists. Diarrhœa is an effort of nature to throw off what the intestines cannot digest. Intestinal ulcers should be assumed to exist in every case, however mild, and the proper treatment of ulcers is rest.

The rational treatment of such a condition is a restricted diet, or fasting, then peristalsis can be better controlled by cold applications, and an opiate may be used, if much diarrhœa exists.

Fasting should be applied from one to three days, until the active symptoms are controlled. The reduction of the degree of toxæmia is hardly noticeable the first day, but is shown by a reduction of one or two degrees of temperature on the second day, and on the third day more than that; but, it is exceptionally advisable to continue fasting through the third day, as the active symptoms are usually ameliorated. In other than sthenic cases, fasting should not be applied, viz., pregnancy, the puerperium, the tuberculous diathesis, the anæmic, etc., but in these cases there is less necessity for its use. One of the greatest arguments to be had for fasting and a restricted diet is, they enhance the effects of hydrotherapy, the technique of which will be referred to later.

Many cases run an abortive course after the amphibolic period under a treatment by fasting and a restricted diet. After fasting twenty-four to forty-eight hours, a very restricted diet should be given, consisting of broths, of beef, chicken, mutton, oysters, etc., coffee, cocoa, egg albumen, pertonoids, etc., in prescribed amounts.

The effect of these slops should be carefully watched, and definite quantities should be ordered in severe cases. It is needless to say they can be taken *ad libitum* in mild cases.

Gelatin is a valuable adjuvant in the dietary of a typhoid patient. It serves three purposes; adds to the relish of the various liquids, lessens the nitrogenous waste from the system, and prevents hemorrhage. A teaspoonful three or four times a day is the amount usually ordered and should be dissolved in a little hot water, and then added to any liquid nourishment, meat broths, cocoa, coffee, tea, etc. It adds a richness of taste to these slops, which otherwise become tiresome to the patient. The food value of gelatin is recognized, and being in a concentrated form serves an excellent purpose. When used, emaciation is less rapid. The hemostatic effect of gelatin is universally conceded, but to wait until an intestinal hemorrhage has occurred, but little immediate good can be hoped for by its use. It should be used as a routine in all cases to prevent hemorrhage. Very aggravated diarrhœic cases don't tolerate it so well, as it may increase tympany. But in these cases it may be used on alternate days in small quantities. Since beginning its use no hemorrhage has occurred.

The case should be closely studied, and any excess of food will be indicated by a rise of temperature. To nourish the patient by a minimum amount of food requires a very close study. Milk should be absolutely forbidden, because no one can predict when it will form a curd, which is worse than any solid food. One of my patients had a hemorrahge in convalescence from taking milk and lime water in equal parts. I examined curds the size of a hazel nut in the bloody dejecta. The case was a mild one.

Another case was seen in consultation 24 hours after drinking two glasses of buttermilk at half-hour interval, with symptoms of perforation. He died three days later from peritonitis. This case was a mild one.

Milk is valuable, however, diluted with two to five parts of coffee, cocoa, broths, hot water, as under these circumstances the danger of curd formation is slight.

This plan of dietetic treatment should be continued until active symptoms are controlled, and, as improvement advances, nourishment may be more liberally given. Solid food is a danger that offers few advantages to the patient. Nearly all recrudescences are due to dietic errors. Fasting in late stages and convalescent stages will cause fever, as inanition often causes fever.

As before suggested, fasting and a restricted diet greatly enhance the effect of hydrotherapy. Where there is fermentation in the alimentary canal with hyperpyrexia, it is easy to understand how difficult it is to reduce the temperature by baths, but under other conditions the modified bath is effective, whether cold, tepid, or hot.

I have often observed a reduction of more than two degrees of temperature after a single sponge bath in a sthenic case after fasting.

To illustrate: In Case 94, which was fasted the first day, and then allowed a very restricted diet. By reviewing the chart from the 4th to the 8th day, there were given 13 cold sponge baths, lasting from 20 to 30 minutes. The greatest reduction of temperature was 2 2-5 degrees, while the lowest was 4-5 degree, and the average 1.8 degree per bath.

Many patients exhibit marked peculiarities as to the effects of cold applications, in most cases having an agreeable effect, during a high temperature, while in others having an exciting effect. The Brand system being more or less impracticable, recourse is had to the modified cold bath, or even a hot bath. Each case should be studied on its own merits, and the cold, warm, or hot sponging applied accordingly.

In fact, some observers[9] have claimed better results from the hot treatment. It has been my observation that cold is better for some, while warm sponging is better for others; and, still, in other cases, cold and hot sponging alternately has been better. In asthenic cases with very high temperature, causing delirium, ice cold applications are preferable, and in later stages, where the temperature is not excessive, but delirium exists, warm sponging has a more soothing effect. In asthenic cases, with hyperpyrexia, the cold and warm alternating seem to act better. Rubbing enhances the effect of these applications and heat is thereby dissipated. It has been stated[10] that 30 per cent. of the entire quantity of blood in circulation remains in the cutaneous system and the intimate relations between the physiologic function of the skin and the temperature variations of the body both throw light on the importance of sponging in typhoid fever. An excess of food in the intestines increases peristalsis and favors the absorption of toxins. The writer has observed an increase of several degrees of temperature in quiescent case by taking a dose of castor oil.

Constipation should be relieved on alternate days by soap-suds enema.

There are many minor details in the treatment of certain symptoms and complications that need no mention, and are familiar to every clinical observer.

I append a chart of an abortive case (No. 108), in which the diagnosis was confirmed on the 11th day by the Widal reaction. On the 3d day there was active delirium, with unconsciousness and diarrhœa, with tympanites. The notes on the chart need no comment.

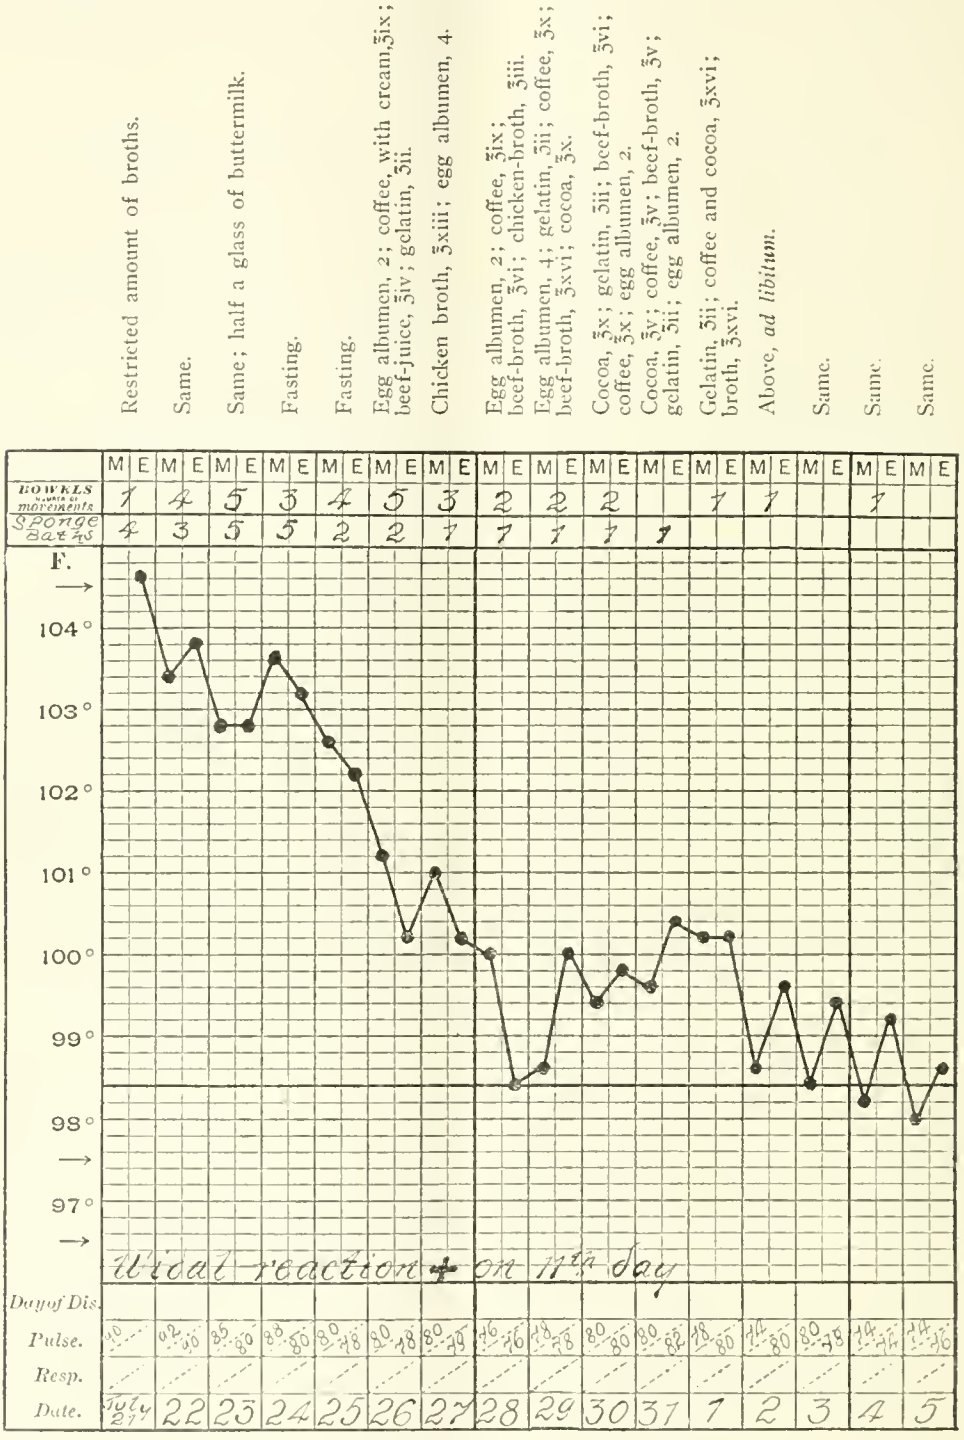

Chart of an Aborted Case of Typhoid Fever: the record begins on the second day of the disease and ends on the seventeenth day.

In this report of cases lasting 12 days, or less, were classified as abortive, and there were 33 cases, or 28.4 per cent. of this type, which is greater than ordinarily expected.

Abortive cases show a greater tendency to relapse, and require to be kept in bed, on a restricted diet, at least ten days after a normal evening temperature.

This series of cases occurred in private practice during a period of eight years, and below is a summary:

One hundred and thirteen were white and 3 were colored. Cases under 10 years old were 26; between 10 and 20, 33 cases; between 20 and 30, 39 cases; over 30, 27 cases. There were 64 males and 52 females.

As to the month of occurrence, August claimed 36, September 28, July 19, October 16, November 8, June 6 and April 3. Gastrointestinal symptoms were marked 45, and absent in 71 cases. Nervous symptoms were marked in 20, and absent in 96 cases. The average duration was 18.3 days; and same, without relapse, was 15.6 days. Five, or 4.3 per cent. of cases relapsed, and all recovered, and the relapses were ascribed to taking solid food too early. Five cases were complicated. Three, or 2.5

per cent., had hemorrhages, two of which were slight, and the third immediately fatal from getting up in delirium. Two cases had two attacks within twelve months.

One case, No. 48, was diagnosed appendicitis, and on the fourth day an apparently normal appendix was removed, and the case pursued a typical course of the disease to recovery.

Case 72 had hæmaturia and recovered.

Case 24 had double parotid suppuration and osteitis of the humeri, and after forty-five days recovered.

Of the four deaths (3.4 per cent.), Case 46, a negro, can with propriety be ruled out, as he was dismissed, and I was called to see him in a relapse, in a dying condition, having had urinary retention 24 hours.

Case 57 would probably have recovered, but being without a nurse she got up in delirium and a fatal hemorrhage resulted.

Case 70 contracted pneumonia on the tenth day of convalescence and died a week later. It was the opinion of my colleague there was no reinfection of typhoid fever.

Case 64, a negro, alcoholic, died on the twelfth day from asthenia.

Of 113 whites treated, there occurred two deaths, or 1.7 per cent.

A summary of these observations may be made as follows:

1. The toxin of the bacillus typhosus is probably produced by bacterial disintegration in the intestinal tract, where the pathognomonic lesions of the disease occur.

2. There is a greater degree of toxemia in cases associated with gastro-intestinal disturbances.

3. The toxin of the bacillus typhosus produces the pathognomonic symptoms of typhoid fever.

4. Hyperpyrexia, without the pathognomonic symptoms, indicates a probability of mixed infection.

5. Different individuals are affected differently by the specific toxin, robust young adults being more susceptible, while the extreme of ages, the anemic, etc., are less so.

6. The variations in types of the disease are more due to individual conditions, rather than types of epidemics.

7. These statistics indicate that there are as many deaths among the mild (2.5 per cent.) as among the severe (5.4 per cent.) cases.

8. Emaciation occurs independently of the amount of food taken.

9. A great majority of clinicians, of long experience, feed typhoid patients in a very restricted manner.

10. Fasting and a restricted diet are indicated, because of pathologic conditions, and to a great extent eliminate the dangers of sthenic cases.

11. The proper food management of the case will well nigh shield him from every danger incident to the course of the disease.

12. The eliminative treatment, so-called, is irrational, except to mitigate the sins of over-feeding.

13. What the patient loses in food is more than compensated by a lessened degree of toxemia.

14. Peristalsis favors the absorption of toxins, and cathartics should be used only to remove undigested food.

15. Nitrogenized food and water are essential to a normal nitrogen equilibrium, and there is little danger from inanition in sthenic cases.

16. The presence of ulcers in the intestines should be assumed in every case of typhoid fever, and the proper treatment is rest, which is better attained by fasting and a restricted diet, thus preventing hemorrhage and perforation.

17. The presence of diarrhœa and vomiting indicates the adoption of fasting.

18. Fasting and a restricted diet enhance the effects of hydrotherapy and many cases (28.4 per cent.) run an abortive course.

19. Gelatin is a valuable adjuvant in the dietetics of typhoid fever, and lessens the nitrogenized waste and prevents hemorrhage.

20. Milk as a food is a danger, except in a modified form.

21. The modified cold bath is preferable to the Brand system.

22. Recrudescences are usually due to dietetic errors.

23. In this report, 45 consecutive cases occurred without a death. Of 113 whites, 2 or 1.7 per cent. died, and the low mortality of 3.4 per cent. of all cases was ascribed to the above treatment.

THE TREATMENT OF PROLAPSE OF THE UMBILICAL CORD.*

By W. REYNOLDS WILSON,
PHILADELPHIA.
VISITING PHYSICIAN TO THE PHILADELPHIA LYING-IN CHARITY

A TEXT-BOOK description of the causes and diagnosis of prolapsus funis is scarcely to be expected before a special society of this character. Prolapse of the cord is a complication that may occur in any case, although certain primary conditions are usually accountable for it. To prove, however, how infrequently such conditions exist as etiological factors it is only necessary to mention them. They include: Deformities of the pelvis, abnormalities in the position of the uterus, the presence of myomata, misplacement of the placenta, multiparity, hydramnios, twin pregnancy, malformations of the fetus, faulty presentation and position.

In the experience of most practitioners probably the last condition, and possibly twin pregnancy, are the only conditions which stand in any way as distinct causes of prolapse of the cord—always reserving, of course, the predisposition to prolapse in premature deliveries. With these two exceptions, therefore, the average conditions in any obstetrical case at the beginning of labor offer no indications as to the occurrence or non-occurrence of this complication. This phase of the subject is that which appeals to the practical obstetrician. This is especially the case in view of the high fetal mortality, which ranges in the neighborhood of 50 per cent.

Before discussing the treatment the exciting causes of prolapse may be mentioned, for the reason that they bear upon the prophylaxis. These are the discharge of liquor amnii and muscular contraction.

Where, by early examination, a faulty presentation or malposition is found to exist complicated by the presence of a loop of the cord, detected through

*Read before the Philadelphia Obstetrical Society, April 7, 1904.

the unruptured membranes, the object in treatment should be to preserve the bag of waters until such time as the position of the fetus may be corrected or until the os is fully dilated. Muscular contraction we cannot control, but the progress of labor can be studiously watched with the object of determining the time at which expulsive pains begin, in order to be prepared to act as soon as the pains threaten rupture of the sac. There should be no exception to the rule that in any case where either the membranes rupture under the observation of the attendant or prior to his receiving the case an immediate examination be made with the possibility of detecting prolapse, irrespective of the history of the case relative to the primary causes of prolapse.

It is not common for the cord to protrude alone into the cervical canal within the unruptured amniotic sac during the early stage of labor before dilatation has advanced. When this occurs the attendant is at a disadvantage inasmuch as active interference is harmful. Yet the chance of the accidents of such a condition are present. Here a sudden early rupture of the membranes is likely to precipitate the cord into the vagina. On the other hand an abrupt tendency to engagement of the presenting part may cause compression. The importance of controlling the fetal heart by auscultation is here manifest. A study of its frequency will point to the degree of compression much more satisfactorily in some instances than vaginal examination. By the latter method the presence of the cord is readily detected, but its pulsation under certain circumstances may be obscured (1) by an undue quantity of jelly in the cord; (2) by edema; (3) by inaccessibility of the cord. A further advantage in controlling the fetal heart by auscultation is the avoidance of frequent vaginal examinations—always a desideratum in management.

I believe for these cases of descent of the cord with imperfect dilatation the proper treatment is to etherize the patient and introduce within the cervix under antiseptic precautions, with care to avoid pressure on the cord, a moderately firm gauze pack. The latter is to be retained by a vaginal pack, which by pressure upon the cervical portion may serve to induce softening and dilatation of the cervix. If the fetal heart be properly controlled the tampon may be left in place until the pains become active, or, if dilatation takes place slowly, the packing may be removed after twelve hours. As soon as the os becomes dilatable manual dilatation with extraction should be promptly undertaken. The method of extraction should depend upon the promptness with which delivery is indicated, (1) by the condition of the heart or the pulsation in the cord; (2) by the character of the presentation; (3) by complicating conditions, such as tetanic uterine contractions or placenta previa. Attempts at artificial reposition with the patient in the knee-chest position before rupture of the membranes is not desirable on account of the danger of evacuation of the sac, although the cord should be displaced from its position in the cervical canal so as to permit the safe introduction of the pack.

If after rupture of the membranes with the cord descended into the cervical canal dilatation is still retarded, manual reposition may be attempted. If, however, the child's condition is unfavorable rapid manual dilatation, even in the earlier stage of labor, should be resorted to without waiting to replace the cord. I have had no experience with reposition by catheter and tape or by artificial repositors. Instrumental dilatation would seem dangerous.

The prognosis of prolapse becomes more unfavorable after engagement when the presenting part fills out the lower uterine segment. As to the various presentations complicating prolapse of the cord, the vertex and face are the more dangerous (excepting the complex presentations). In the first instance for the reason that reposition before engagement is apt to be unsuccessful, while after engagement the danger of compression is very great. The necessity of applying forceps in vertex presentation is accompanied with more or less danger to the child and can be carried out less quickly than version. Although the latter procedure may be thought of after engagement it is not so desirable as when undertaken before the head has entered the inlet. Therefore if the case is seen early, or to put it differently, if the prolapse is discovered before engagement of the head version may be undertaken, but in the majority of cases the time for this is often allowed to slip by either in resorting to attempts at reposition or in failure to make the diagnosis of prolapse.

In facial presentation it is desirable to perform version at the proper moment, guarding against delay when once the membranes are ruptured in order to escape the danger to the mother of turning while the uterus is in tetanic contraction. It must, however, be admitted that successful version under these conditions is not easy of accomplishment, for the reason that the conditions are most difficult owing to the fact that prolapse of the cord occurs usually with engagement, or at least, is not likely to be recognized before engagement, when it is too late to perform version. Again, early rupture of the amniotic sac in face presentation usually allows of the more or less complete evacuation of the sac, which in turn is followed by uterine spasm, rendering version most dangerous to the mother. When the face has entered the pelvis and labor is progressing our only recourse is the application of the forceps, avoiding as much as possible injury to the cord.

Breech presentation offers less danger than vertex and face presentations, except in frank or simple breech cases. The child is then in such position as to permit usually of rapid extraction when the diagnosis is made. The fact is, in prolapse of the cord in breech cases we can count on the absence of one complication which frequently costs the child its life in pelvic presentation, namely, winding of the cord about the neck, as it is improbable that the cord be long enough to permit of the double complication of winding and prolapse. The greater danger in these cases exists, in contrast to vertex presentation, in the liability to early rupture of the membranes, which offers an opportunity for descent of the cord. In the early stage of labor, before dilatation has advanced, premature rupture of the membranes should be guarded against and the parturient should be placed on that side opposite to the pelvic position of the cord. The method of dealing with prolapse of the cord when dilatation is advanced is to disregard the cord, if after an attempt at reposition the cord again prolapses, and to deliver promptly by extraction. It has not been my experience to find the extension of the arms above the head a dangerous element in the latter stage of extraction. Greater danger than this lies (1) in the difficulty in flexing the head in order to deliver it; (2) in coiling of the cord about the neck. It is fair to say that both of these conditions may exist in breech cases as a complication independent of the method of artificial delivery—the first as a consequence often of a contracted pelvis, the second as an unpreventable accident. It is, of course, possible to conceive of cases in which prolapse may occur at a stage where it would be inju-

dicious to attempt rapid extraction. Here manual reposition may be attempted, followed by the withdrawal of the anterior foot if possible, in order to fill out the lower segment of the uterus and stimulate dilatation of the os. If this procedure is followed auscultation must be frequently resorted to, as the cord, although not prolapsed, may still be compressed by the engaging part.

In all cases before operating the whole hand should be introduced into the uterus, after etherization, in order to determine the attitude of the fetus and to disengage any loop of the cord which may be encircling the thigh or buttocks.

Before engagement with the amniotoic sac intact I can see no advantage in cephalic version by the Braxton-Hicks method. The danger of rupture of the membranes is certainly increased by such manipulation. It is well also to recall the fact that a large majority of instances of prolapse of the cord in breech presentations occurs as a complication of premature labor, when, owing to the size of the child, it is easier to extract by the breech than to apply the forceps to the head after cephalic version.

In shoulder presentation, if the case is seen early two essential points in treatment present themselves: (1) examination at the moment when the membranes rupture; (2) podalic version with extraction after manual dilatation, when the cervix is not fully dilated. In prolapse of the arm complicating descent of the cord the prognosis is necessarily bad, although podalic version, without regard to the position of the arm, under complete anesthesia, offers a chance of saving the child.

In discussing the treatment of this condition it would appear that the most favorable results are offered by resorting to prompt delivery. This can be accomplished in suitable cases by manual dilatation followed by direct version rather than by attempts at reposition either by posture or by mechanical means. It appears that we are dealing with a condition that offers almost as unfavorable a prognosis for the child as placenta previa. Therefore radical means are called for by the gravity of the conditions. The prognosis is so favorable for the mother that it is apt to obscure the necessity for serious consideration for the child's welfare. We are apt to look upon prolapse of the cord as a complication which may be treated expectantly, as long as pulsation can be detected, forgetting the danger of sudden compression. It is in fact more excusable to suffer the death of the fetus from coiling of the cord (which in most instances cannot be foreseen) than from prolapse in those cases where an early diagnosis may point the way to version with prompt delivery.

1709 Spruce Street.

FORMOL-IODINE, A MODIFIED CLAUDIUS METHOD FOR THE PREPARATION OF CATGUT.

By WILLARD J. STONE, B Sc., M.D.,
TOLEDO, OHIO.

Following Claudius' reports[1] of the satisfactory method used in Bloch's clinic, Copenhagen, and in this country after Senn's article of commendation, sterilization and preservation of catgut by means of Claudius' iodine solution has been the procedure more or less generally adopted. This method, which produces an easily prepared aseptic suture material of fairly good tensile strength, consists in submerging the gut for eight days, after winding on glass spool or wood chip, in iodine, 1.0; potassic iodide, 1.0; distilled water, 100.0. The potassic iodide is first dissolved in a small amount of water, the pulverized iodine crystals then added to it, and the mixture diluted to 100 cc. with distilled water.

This method is to be especially commended because of the ease with which an absolutely aseptic gut can be prepared, as evidenced by repeated bacteriological tests, and without the preliminary treatment formerly considered necessary for the removal of fat from the raw commercial material. Moreover, since the sterilization and preservation is accomplished by the one solution, it obviates the necessity of handling and changing the sterilizing solutions—with the chance of coincident contamination—common to most of the methods in vogue.

Claudius recommends washing the gut in a 3 per cent. carbolic solution just before using, which is supposed to increase its tensile strength.

The reports of those who have adopted the method have been for the most part favorable to it.[2] They have agreed upon the following points: Its absolute asepticity, its ease of preparation, that it knots well, and that the amount of iodine impregnated in the gut not only serves to keep it sterile, but exerts, because of its power of diffusion, a marked antiseptic action upon the tissues in the immediate vicinity. It is a little more durable in the tissues than alcohol catgut.

Moschcowitz has reported the entire efficiency of catgut so prepared, during its use for seventeen months in Mt. Sinai Hospital, New York. Senn has used Claudius catgut for months in his service at St. Joseph's and Presbyterian Hospitals, Chicago, with entire satisfaction. Martina used iodine catgut in seventy cases; the healing was by primary intention in all but two, and in these the suture material could not be considered at fault.

Other writers, on the other hand, have condemned its use.[3] The point of dissension has seemed to be in regard to the tensile strength of catgut so prepared. Martina found that in some cases the gut fibers tended to separate after five or six days in the solution, and therefore that it was not so suitable for use in herniotomies, etc. Emerson has tried the method, but has not been satisfied. He has found the gut too elastic and brittle. E. J. Senn has replied to this criticism by saying that with inferior raw material such a result may be excepted, for, in the clinic, they have had similar experiences. N. Senn has found the catgut made in this country more suitable for iodine sterilization than the imported material.

Van Hook has found that Claudius catgut does not have an agreeable handling quality, and that it becomes fragile and loses tensile strength on storage.

Salkindsohn has stated that iodine catgut loses its firmness in time, but that otherwise it has all the requirements of a perfect suture material. He did not adhere rigidly to the Claudius solution, since he used 10 parts of potassic iodide instead of 1. This probably did not seriously affect the result. It has been somewhat difficult to see how washing in carbolic solution just before using, for the short time recommended by Claudius, could increase the tensile strength of the gut, since the solution does not harden the individual fibers or render them more compact.

By using the following modification of the Claudius method, the tensile strength of catgut is greatly increased, *i. e.*—the tensile strength depending upon the hardness (durability) *plus* elastic pliability of the gut fibers, and secondly, its resistance to dissolution in the tissues is increased. It resembles chromicized gut in this particular. The point is taken that if a small caliber of gut is found to be equal in

tensile strength to a larger caliber preparted by other methods, providing it is not of such small size as to cut through the tissues, the smaller size would have preferable usage. In addition, the continued presence of suture or ligature material, providing its asepticity is assured, for a somewhat longer length of time in the tissues than has been considered necessary, *i. e.*, artery ligatures, merely aids in increasing the safety and efficiency of the procedure.

The modification consists simply in submerging the raw commercial catgut in an aqueous 4 per cent. formalin solution for thirty-six to forty-eight hours, then washing in running water ten to twelve hours to free the excess of formalin, and then to submerge in the iodine solution recommended by Claudius for eight days before using. The gut should be loosely wound on glass spools and put in the formalin solution. When in the running water, strands ten to twelve inches long are cut from the spool and put into the iodine solution. The writer has found that, providing a certain batch of catgut is old and brittle, the addition of 5 per cent. solution boroglyceride (glycerite of boroglycerin U.S.P.) or of glycerin, to the iodine solution, improves the pliability of the catgut without in any way lessening its tensile strength. The boroglycerin, or glycerin, should be sterilized in a container surrounded by boiling water for one-half hour on three successive days. Scrapings from gut prepared in this way have been found to be absolutely sterile in one-half hour after submersion in the iodine solution.

The material is left in the iodine, or iodine-glycerin solution, until ready for use. It is then removed with sterile forceps, threaded and placed in sterile water. It seems to be preserved indefinitely in the solution without suffering deterioration. The formalin treatment is not intended to render the gut sterile, although it undoubtedly aids in the process, but merely to harden it. The addition of the boroglyceride, or glycerin, when necessary, to the iodine solution, is intended to render the gut more pliable after the hardening process.

Catgut so prepared has all the requirements of a perfect suture and ligature material. It is stronger than any ever seen by the writer when prepared by other methods. It practically has the tensile strength of silk, in fact. It is pliable, and not too elastic, knots well, and seems to be ideal in every respect.

STROPHANTHUS IN LOBAR PNEUMONIA.

BY C. AM ENDE, M.D.,

NEW YORK.

IN a recent elaborate review upon lobar pneumonia, J. M. Ferrer[1] enumerates with brief criticism all processes and drugs employed in lobar pneumonia, with the exception of strophanthus. At the Atlantic City meeting of the American Medical Association neither Wells nor Tailer spoke of it, and the only mention the writer is aware of is, except one by himself in a discussion, one by W. Gilman Thompson.[2] As its employment in the writer's hands was followed by a favorable termination of all his cases on the fifth day, and as it is a drug readily obtainable everywhere, a few remarks upon it may be of wider interest.

With the tendency in this city to rush all patients into a hospital, the number of my cases is small, far too small for a general deduction; still with about twenty-five it would seem large enough for recommending this treatment for further observation, and probably improvement where facilities abound. This so much more, as these cases comprise quite a variety of conditions and complications from a 2½-year-old tot to a poorly nourished woman of 67—from a robust, sober young man to an inveterate old toper, who, after 48 hours of delirium tremens, added a left lobar pneumonia to his other little difficulty.

The necessity of sustenance of the heart having, now many years ago, been urged especially by A. Alexander Smith as the all important object in pneumonia, the question occurs, why, then, wait until the heart begins to flag or fail, and not tone it up and strengthen it from the beginning for the severe task ahead?

The administration, then, for this purpose of strophanthus, immediately upon the establishment of a diagnosis, proved in the very first case equally satisfactory to patient and doctor, and so has continued ever since; the dosage, of course, has varied according to circumstances.

Naturally other supporting measures and drugs were employed: strychnine always; nitroglycerin usually; oxygen occasionally; of the latter nearly a full cylinder in the delirium case; the intelligent wife, this man's only nurse, administering it every time the pulse would perceptibly weaken. This man's temperature, repeatedly above 105°, dropped on the evening of the fifth day to near normal, and two days later the delirium also subsided.

A very peculiar case occurred in a younger man, the sole support of a large family. As the consequence of prolonged absence from work would have been most serious, minim doses of strophanthus were administered every hour with full doses of aromatic spirits of ammonia, with the result that within about twenty hours the well-developed symptoms of the first stage had all disappeared, and the man returned to work four days later.

In a subsequent case lysis seemed to set in on the third day; the temperature was near the normal on the fourth; but on the fifth day an alarming, painful recrudescence occurred for about eight hours. Termination by lysis had been observed in a few earlier cases when the diagnosis was very carefully verified. Thompson also observed lysis.

Whether administration, *ab initio*, of other heart tonics would give similar results in lobar pneumonia, is a question which I did not feel justified in determining by experiment.

Studious Royalty.—Few people realize the amount of educating that goes to the making of a continental ruler. One of the most studious queens in Europe is the German Empress, who cares but little for the pomp and ceremony of courts. Her Majesty's favorite study is medicine, and she has instructed herself so well in the art of healing that she is regarded as quite an efficient adviser in cases of ordinary illness.

THE EARLY DIFFERENTIAL DIAGNOSIS OF TYPHOID FEVER.

ON account of the inexpensiveness of attendance upon "sick call," the army surgeon has an excellent opportunity of seeing diseases in the earliest, even in the incubation, stages. This fact lends special interest to the article on the above subject in the *Journal of the Association of Military Surgeons* for September by Dr. W. C. Rucker. By "early" is meant the incubation period plus the first week.

The differential diagnosis of a disease presenting such a multiformity of aspects as typhoid fever is necessarily difficult, and especially in the earliest stages, when few infectious diseases present such great variations in their manner of onset. The diagnosis is further complicated by the fact that various organs may bear the brunt, the predominant symptomatology being pulmonary, renal, or nervous, and at the same time the disease may present itself under an abortive, mild, severe, hemorrhagic, or ambulatory type. The ill-defined languor and indisposition, mental depression, headache, vertigo, sacral pain, anorexia, and irregularity of the bowels, in the absence of fever and physical findings, are, however, in sharp contrast to the initial period of other febrile diseases which, during this stage, generally present no manifestations. In those cases which come under close observation careful examination of the temperature curve may disclose wide daily fluctuations, even though fever be absent. This, in connection with the symptoms, will often put the careful clinician on the road to an early diagnosis. Epistaxis is of value merely as part of the symptom-complex, but it occurs with far greater frequency in typhoid than in many other diseases which come into the differential diagnosis. It occurs in seven per cent. of the cases, most frequently during the incubation period or at the onset. Its value is lessened chiefly by its early occurrence in cerebrospinal meningitis and acute miliary tuberculosis.

The first febrile symptoms mark the onset, and are accompanied by slight, oft repeated, chilly sensations. So regular is this that a hard chill with a sharp rise of temperature usually eliminates typhoid fever at once. The temperature rises gradually with slight morning remissions, and at the end of the first week usually reaches 104° F. The curve of these step-like gradations is of great diagnostic weight, but though this is typical for typhoid fever there are occasional cases with a sharp initial rise in all respects similar to that of other infectious diseases. Remittent malarial fever presents a very irregular curve, while typhus, relapsing, and scarlet fevers, measles, and smallpox exhibit sharp initial rises; and in intermittent fever these are paroxysms hardly to be mistaken for the steady progression of typhoid. The closest resemblance of febrile curve occurs in Malta fever, and with a history of exposure elicited, the differential diagnosis in the majority of cases is impossible without the microscope and the serum test.

The pulse rate in typhoid, while strikingly parallel with the temperature curve, is relatively infrequent, not attaining the rapidity usually observed with like degrees of temperature. In no other febrile disease does this occur with such regularity. By the fourth or fifth day the pulse is already dicrotic, and usually remains so. This occurs more often in typhoid than in all other infectious diseases together, and is of great diagnostic value. Thus Oddo and Audibert found it in thirty-four out of fifty cases examined.

Of great diagnostic import is the roseola which appears during the second half of the first week, distributed over the abdomen, chest, and neck. Though the eruptions of other infectious diseases sometimes resemble this, they rarely deceive an experienced observer. In combination with the state of the spleen and bowels, the time of appearance and subsidence, its succession of crops, characteristic distribution, and efflorescence, it is perhaps the most valuable single sign of the disease. Its value is enhanced by its not being, as are most of the papular rashes of the exanthemata, preceded by an evanescent erythema. The eruption in typhoid fever appears later than in any other exanthematous disease—on the sixth or seventh day. The lesions of typhoid roseola are papular, bright pinkish-red, rarely coalesce, disappear on pressure, come out in successive crops, and when typical are raised above the surrounding level. Recently Gibbes has by special photographic methods succeeded in detecting the eruption several days before its visible development. Drug rashes hardly come into the diagnosis; that of copaiba is most often on the extremities, and lacks the bright hue of the typhoid; it appears suddenly, itches, and disappears on withdrawal of the drug; quinine, atropine, and turpentine rashes are scarlatiniform, the last being blotchy and only rarely resembling that of typhoid fever.

From the beginning there is a progressive hypoleucocytosis in marked contrast to the hyperleucocytosis usual in pneumonia, cerebrospinal meningitis, sepsis, and other diseases.

Though splenic enlargement occurs in all infectious diseases, it is of special significance in typhoid. Though it has been reported during the period of incubation, it is very unusual before the middle of the first week. But if we except Hodgkin's disease, malaria, and typhus, in which it occurs in the first days, in few infectious diseases does it occur so early or persist so long.

The diazo reaction occurs first from the fifth to the thirteenth day. Though present at times in pneumonia, scarlatina, variola, measles, septic conditions, and advanced malignant disease, its absence in a case closely simulating typhoid fever points rather against the latter.

The absence of profuse sweating, herpetic erup-

tions, jaundice, coryza, conjunctivitis, and vomiting is to be noted. Any one of these is rather a caution mark against a diagnosis of typhoid. In particular, coryza symptoms (sneezing, conjunctival catarrh, etc.) are among the greatest exceptions in typhoid, and a predominating coryza would speak rather for typhus or influenza.

As tonsillitis and laryngitis occasionally occur early and the bacillus of Eberth has repeatedly been isolated from these organs, the initial infection may in some cases take place through them.

The author discusses at some length the bacteriological questions involved. In particular, he quotes with approbation from the method of Wolff of Hartford, which combines the Widal serum reaction with the culture of the bacillus from the stools. Also the bacteriological methods for isolating the bacillus from the blood and that of Seeman for isolating it from blood taken from the rose spots are discussed. As an evidence of the value of the bacteriological examination of the blood it may be noted that Schottmüller in 119 cases discovered the bacillus of Eberth in the blood in 84 per cent.; in one case as early as the second day, and in a great many cases before the Widal test was positive.

After giving those valuable differential points between typhoid fever and the several diseases most likely to be confounded with it, the author concludes that there is no single symptom on which alone an early diagnosis can be based; it is only by a careful consideration of the symptom-complex that a clinical diagnosis can be arrived at. The most trustworthy as well as the earliest sign is the presence of the bacillus of Eberth in the circulating blood, and its demonstration there is not beyond the reach of the resources of any well equipped laboratory. The bacillus is found later in the fæces, and with comparative ease, its presence there being a valuable corroborative sign. The Widal reaction is rarely demonstrable in the earliest stages.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

The report of the Surgeon-General of the United States Army, for the fiscal year ending June 30, 1904, has just been issued. The health of the army during the past calendar year has been very satisfactory, the admission rate per thousand of strength showing an improvement over that of 1902, the rates being 1,451.13 and 1,716.51, respectively. This result has been brought about by the more careful attention given to sanitary matters.

The number of cases and rates per thousand of mean strength for disease in the army, reported in the calendar year 1903, were as follows: Admissions, 83,096, rate, 1,228.45; discharges for disability, 1,462, rate, 21.61; deaths, 475, rate, 7.02. Those for external causes: Admissions, 15,063, rate, 222.68; discharges for disability, 120, rate, 1.77; deaths, 154, rate, 2.28.

The admission rate in the United States per thousand for disease and injury was 1,206.89 and death rate 5.94, compared with 1,343.77 and 7.83 in 1902. Of this rate 961.50 men per thousand were admitted and 4.12 died from disease, and 245.39 admitted and 1.82 died from external causes.

The Pacific Islands and China furnished 44,767 admissions to sick report during the year, equivalent to a rate of 1,879.54 per thousand men, of which 53 were discharged on surgeon's certificate of disability and 375 died, giving rates of 2.23 and 15.74 respectively per thousand of mean strength. From Cuba and Porto Rico 2,384 admissions to sick report were reported, equivalent to a rate of 1,527.23 per thousand of mean strength, with rates of discharge for disability and death of 19.86 and 1.92, respectively.

The portion of the report, perhaps, which will give the greatest satisfaction is that which refers to the decided decrease of cholera in the Philippine Islands. This favorable state of affairs is undoubtedly due to the untiring efforts of the army medical officers in preventing its spread among the troops serving at the island stations. The improved health conditions prevailing among the United States troops is almost entirely owing to the advances made in sanitary matters since the war. A large proportion of the soldiers have been on practically war service in the Philippine Islands since 1898, yet the rates of sickness during the past year have been lower than at any time since the outbreak of the Spanish-American War. The mean strength of the whole army for the year 1903 of 67,643 men consisted of 59,671 white troops, 3,183 colored, and 4,789 native Filipinos. Of these the negroes show the lowest figures in sickness, while the white troops had by far the lowest mortality and the most sickness. The Filipinos had the highest mortality rate, almost double that of the negroes, and an admission rate which closely approached the high rate of the white troops.

Typhoid fever showed a gratifying decrease, as also did malarial fevers. The prevalence of tuberculosis varied but little from that of previous years. There were 636 cases of beriberi, nearly entirely confined to the Filipino soldiers, while of bubonic plague during the year 1903 there was not a single case. A further reduction in intestinal affections among the troops was noted. The number of admissions to sick report, however, for venereal disease during 1903 remains large. Although the admission rate for the whole army was slightly lower than that of the preceding year, the ratio of discharge per thousand of strength was a little in excess of 1902, and a total of 4 deaths was reported.

Three cases of wood alcohol poisoning were reported, with two deaths, both occurring in less than twenty-four hours. A slight decrease in the number of admissions for alcoholism is noted. Of the total number of admissions 1,541 were for acute alcoholism, 73 for chronic, and 56 for delirium tremens, equivalent to 22.78, 1.08, and 0.83 per thousand men. Of the 42,264 troops serving in the United States, 1,041, or 24.63 per thousand, were admitted for acute alcoholism, of which 6, or 0.14 per thousand, terminated fatally. For troops serving in Cuba and Porto Rico a higher rate than the large one of last year was reported. The rate of admission for acute alcoholism was 51.25, or nearly three times as great as the corresponding rate for the troops in the Pacific Islands and China. A slight increase in alcoholism occurred in the Pacific Islands and China over the rate of last year. Insanity was far less prevalent during 1903 than in the previous year.

The report lays emphasis on the fact that on account of the lack of medical officers, very few

are available for the examination of recruits, and this important duty is in consequence largely delegated to civilian physicians. These civilian medical men are ignorant as to what should be the physical characteristics of recruits, and their inability to fulfil their duties properly entails much expense and loss of good material to the Government. Many men are accepted who are unfit and *vice versa*. The report thus refers to this subject: "The physical examination of recruits is a specialty, the mastery of which requires instruction, study, and experience. It is not a branch of general medicine in which civilian practitioners can be expected to attain the results of qualified officers of the Medical Department. The efficiency of an army depends largely on the physical fitness of its recruits, and for their examination the technical skill of a physician in active practice, with knowledge of the requirements of the service—in other words, the skill of a trained medical officer is needed, who should be held to a strict accountability for accepting physically unfit men."

The report adds the usual testimony regarding the incalculable evil resulting from the abolition of the army canteen. It has been argued time and again, in both medical and lay journals, that the abolition of the canteen was a mistake of the gravest nature. This contention has been borne out by facts. Since the canteen was done away with, alcoholism has increased greatly in the army. Men who wish to drink will procure alcoholic stimulants by hook or crook. The canteen provided wholesome beverages, and was moreover a decided check upon the tendency to the abuse of alcohol. At the present time the stimulating beverages available to soldiers can be obtained only in saloons of a low character, in which liquors adulterated or of a low grade are sold, and in which all restraint is thrown aside. The consequence is that drunkenness is more rife in the army than ever before. The testimony of the majority of army medical officers is that the abolition of the canteen has been attended with evil results regarding the health and morality of the soldiers. It has been a striking instance of the harm done by the zeal of well-meaning persons being directed into wrong channels.

The Air of the Subway.

Among the many criticisms of the subway construction and management, the one which most imperatively calls for investigation is the statement that the system of ventilation is defective. According to the newspapers, several physicians have been collecting and analyzing samples of air taken on the platforms of the various stations, and have found the percentage of oxygen to be anywhere from 12 to 17, that at the City Hall station being the highest. The air at the level of the street contained at the same time about 20 per cent. of oxygen, or little less than normal. Assuming that these analyses were correct and that the published results show the average condition of the air in the subway, the need for a better system of ventilation would be evident. The reduction in the amount of oxygen would not in itself be dangerous, for an atmosphere containing 12 or 13 per cent. of oxygen is fit to support life indefinitely, but the increase in carbon dioxide, if proportionate to the oxygen loss, would be a matter of concern. But it is by no means certain that an analysis carefully made by a competent chemist would give any such results as these; and whatever the constitution of the subway air it surely cannot be so bad as that of the London underground railway, with its coal-burning locomotives, or even that of the "tuppenny tube," and a good many persons ride in those tunnels every day without apparent injury to health. However, the question is one that should be authoritatively determined by experts under the direction of the Health Department, and if the ventilation is so defective as to constitute a menace to health, the fact should be made known and remedial measures should be instituted without delay.

Death of Dr. Niels Finsen.

With the death of Dr. Niels Finsen a remarkable man passes away. He first came prominently into public notice by his discovery that light might be produced by mechanical means whereby lupus and other skin diseases might be successfully treated. Finsen sought to apply the well-known fact that sunlight is fatal to the germs of certain diseases and especially to the bacilli of tuberculosis. He asserted that he had discovered the essential bacteria-destroying principle of sunlight in the violet and ultra-violet rays, and perfected an electrical apparatus which threw off none but these rays.

The "Finsen rays" are largely used in many of the large hospitals of the world, the London Hospital in the east end of that metropolis having perhaps the most complete light equipment which can be found anywhere. The treatment has proved itself on the whole satisfactory, although it has not altogether fulfilled the expectations of its founder. Finsen also devised, or rather brought again into use, a method for preventing pitting in cases of smallpox. He believed that the suppuration of smallpox was largely if not wholly brought about by the action of sunlight. He accordingly reintroduced the treatment of smallpox by the red rays of light. Sunlight is shut out of the room in which lies the patient suffering from smallpox, only the red rays being admitted. Finsen tested this method himself in a comparatively small number of cases, and the theory can hardly be said to be proved, as the experiments have not been on a sufficiently wide scale.

Dr. Finsen received the Nobel prize in 1903 given to the person who has done the greatest work for the advancement of mankind. The deceased scientist was an admirable type of the unselfish investigator. He was a simple, kindly man, who cared little for fame or money, but was wrapped up in the work of his special field. He leaves an honorable untarnished name as a monument of his labors. In his life he was greatly loved by his fellow countrymen, and his memory will be revered on account of his high personal qualities as well as because of his great scientific attainments.

A Plea for the Oyster.

Some of the lay journals have lately published reports, sent in a curiously roundabout way by the United States Consul-General at Frankfort, of the findings of the French Sea Fishery Commission appointed to investigate the part played by the oyster in transmitting typhoid fever and various other diseases. The conclusion the commission is said to have reached is that oysters may be eaten with impunity at all seasons, and that they cannot transmit disease to human beings. The recent work of our own city Board of Health has shown that the conditions under which oysters intended for the market are often fattened in stagnant water

in close proximity to outhouses and the mouths of sewers are, to say the least, disgusting in the extreme, and even if there were no real danger, public sentiment should be kept awake to the undesirability of such procedures until their continuance has been rendered impossible. But, as a matter of fact, that there is danger of spreading typhoid fever by means of oysters fattened in sewerage-polluted streams has been abundantly demonstrated both in this country and in England, and the wide publicity given to the American consul's translation from a German newspaper of a translation from a Paris newspaper of the alleged findings of a committee appointed by the French Minister of the Navy seems to be rather in the interest of the oyster trade than in that of the public health.

A New Typhoid-Fever Serum.

At the French Medical Congress, held in Paris the latter part of October, Professor Chantemesse read a paper giving an account of the results obtained by a new antiserum in the treatment of typhoid fever. The serum is prepared by injecting soluble typhoid toxin into the horse, according to a method described by the author in a paper read at the International Congress of Hygiene, in Madrid in 1898. He has been using this serum in his service at the Hôpital du Bastion 29, for three years and a half, treating in that period 545 cases, with only 22 deaths, showing the remarkably low mortality (for Paris hospital cases) of 4 per cent. During the same period there were treated by the usual methods, in fourteen of the Paris hospitals, 3,199 cases, with 581 deaths, showing a mortality of practically 18 per cent.

As to the mode of action of this serum, Chantemesse says it exerts a rapid and energetic specific effect upon the defensive apparatus of the organism—the spleen, the lymphoid tissue, and the bone marrow. The stimulation which it produces is the greater and more effective the earlier in the course of the disease it is used. The organism must be still capable of reaction, and if the nervous system is already profoundly depressed, the benefit of serum medication is much less evident. Its mode of employment is very different from that of diphtheria antitoxin. In the case of diphtheria, the more severe is the disease the stronger should be the dose of antitoxin; but the reverse is true, Chantemesse says, in the case of the typhoid serum which he employs, for the more profoundly the patient is affected the weaker must be the dose of serum.

Railroad Death Record.

The last quarterly bulletin of the Interstate Commerce Commission contains what is termed "an alarming exhibit" of the record of railway accidents for the twelve months ending June 30, 1904. Altogether there were 55,130 casualties, 3,787 killed and 51,343 injured. This is an increase over the previous year of 5,599 casualties, or 233 killed and 5,366 injured, and makes a new record in disasters. These figures do not include accidents at highway crossings, to trespassers or persons walking along the tracks, in shops remote from the railroad, or to employes not actually on duty. Accidents of this nature always add several thousand to the total.

It is interesting to note that but three accidents occurred on roads provided with block signalling apparatus, and that these involved the loss of three lives, whereas the roads not furnished with this system continue to contribute increasing lists of casualties to the records.

News of the Week.

Medical Society of the State of New York.—Before closing the program which is in preparation for the approaching meeting of the Medical Society of the State of New York, which is to be held the last in January at Albany, the committee requests all who intend to read papers to communicate with it soon. The committee, as already announced, is composed of Drs. Henry Flood, of Elmira, chairman; A. Edward Davis, of New York City, and L. H. Neuman, of Albany, secretary, to any one of whom anything relating to the matter may be addressed.

The Fifth New York State Conference of Charities and Correction will be held at Syracuse, November 15 to 18, 1904, under the presidency of Robert W. Hibbard, Esq., of Albany. The subject of discussion on Friday morning, November 18, will be "The Mentally Defective." The following is the program for this session: Report of the committee by the chairman, Dr. Eugene H. Howard, Superintendent of the Rochester State Hospital, Rochester. Paper, "Importance of Recognition and Appropriate Care of Distinct Phases of Mental Defect," by Dr. William L. Russell, Medical Inspector of Institutions for the Insane, Poughkeepsie; Discussion opened by Dr. Robert B. Lamb, Medical Superintendent of the Dannemora State Hospital, Dannemora. Paper, "Duties and Responsibilities of Managers, Visitors, and Trustees of Institutions for the Care of the Mentally Defective," by Daniel B. Murphy, member of the Board of Managers of the Craig Colony, Rochester: Discussion opened by Dr. Charles Bernstein, Superintendent of the Rome State Custodial Asylum, Rome. At the close of the Conference there will be excursions to the George Junior Republic at Freeville, the State Prison at Auburn, the Onondaga County Penitentiary, the Onondaga County Almshouse, and other nearby institutions.

The Bellevue Superintendency.—The Municipal Civil Service Commission will soon, it is said, take up officially the discussion of an examination for the superintendency of Bellevue and Allied Hospitals. For the last six months the hospital has been in charge of Michael J. Rickard, assistant superintendent. When Dr. Mabon left Bellevue to take a place in the State Lunacy Commission, the Board of Trustees named Dr. William P. Spratling, head of the Craig Colony for Epileptics, as the new superintendent. The State Civil Service Commission certified Dr. Spratling, but the Municipal Civil Service Commission would not let him take the place without an examination, and the examination was not prepared.

The State Civil Service Commission announces general examinations to be held December 3, 1904, for the positions of physician, fourth grade, State hospitals and institutions, and resident physician, State Industrial School, Rochester. Applications for these examinations must be made on or before November 28. Full particulars of the examination and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

The Effects of Preservatives on Health and Digestion.—Dr. W. H. Wiley, Chief of the Bureau of Chemistry in the United States Department of Agriculture, delivered at Philadelphia on November 4, under the auspices of the Franklin Institute, a lecture entitled, "The Results of Experimental Studies of the Effects of Preservatives on Health and Digestion." He pointed out that various methods of preserving food have been practised since earliest times.

Among such methods are the removal of water and the use of certain condimental substances, such as salt, sugar, vinegar, and wood-smoke. More recently sterilization of food by heat and the exclusion of germs has been practised and constitutes one of the safest and most approved methods of preservation. Still more recently a system of food preservation has grown up, based on the use of so-called antiseptics which have the power of inhibiting or destroying the germs of putrefaction. The more common of these are boric acid, borax, salicylic acid, benzoic acid, sulphurous acid, and formaldehyde. There is a wide difference of opinion among physiologists and chemists as to the effects of such substances. In order to clear up the matter a series of experimental observations were made for a period of nine months under the auspices of the Department of Agriculture, borax and boric acid being added to food, beginning with small amounts (9½ grains) and gradually increasing them to from 45 to 60 grains daily. It was found that the maximum amounts caused disturbance of digestion and derangement of health, as manifested by impairment of appetite, loss of weight, a feeling of uneasiness and sometimes of pain in the stomach, a sense of fulness in the head, often developing into a dull and persistent headache, a general disturbance of the metabolic activities of the digestive organs, and other unpleasant symptoms. When the small amounts were employed for a long time similar symptoms developed, though in lesser degree. It may, therefore, be concluded that while the injection of small amounts of borax occasionally with the food would do no permanent injury to an ordinary healthy individual, it might prove distinctly hurtful under the reverse conditions. Corresponding observations have been made with salicylic acid, benzoic acid, and sulphurous acid, but the results are not yet ready for publication, and studies upon the effects of formaldehyde and various coloring matters on health and digestion are to be made.

Free Treatment by the Medical Faculty of the University of Michigan.—The Regents of the University of Michigan have ruled that the medical faculty of the University of Michigan must grant gratuitous medical and surgical treatment to everybody applying therefor, whether rich or poor. This has led the Wayne County (Mich.) Medical Society to pass resolutions declaring that such a ruling deprives the medical citizens within the radius of the influence of the University of Michigan of part of their rights in an unwarranted manner, and is harmful to the State as well as to the medical profession, and calling upon the Board of Regents of the University of Michigan to rescind its ruling concerning the indiscriminate free medical and surgical treatment of those who apply for treatment at the University clinics.

To the Druggists of Rome.—The following circular note has been sent by the Rome (N. Y.) Medical Society to the druggists of that town: "It is with a deep feeling of regret that we, as physicians of Rome, organized into a city society for the promotion and improvement of the public health, and depending on the druggists of Rome to assist us therein, frequently notice in the local press glaring advertisements of 'cure all' remedies. These advertisements mislead the public and react adversely to the object which the local society is (and the druggists should be) endeavoring to promote. We believe the druggists and physicians should co-operate in working for the betterment of the public health, and that such notices in the papers as we refer to are distinctly detrimental to the public health, and that all true pharmacists should see to it that such misleading statements do not appear over their individual or firm signature. Respectfully submitted as per resolution of the Rome Medical Society. C. A. Frost, M. D., and Charles Bernstein, M. D., Committee."

Suit Against Milk Dealer.—The State of New York has caused papers to be filed in Buffalo bringing suit against a milk dealer to recover $14,900 for alleged violation of the law covering the sale of adulterated milk. Milk from this dairy is supposed to have caused a recent outbreak of scarlet fever. The State's complaint contains 149 specific counts against the defendant, on each of which counts the State seeks to recover $100.

Harvard Training School for Nurses.—It is announced that a training school for nurses is to be added to Harvard University under the direction of Dr. Alfred Worcester, of Waltham. Dr. Worcester has just returned from a six months' trip in Europe, where he was sent by the University for the purpose of studying the various training schools in Germany. The course is to be one of four years, and is to comprise both hospital work and training experience in private homes.

Alien Asylum Patients.—According to a communication from San Francisco a report from the local United States immigration inspectors has been forwarded to the commissioner of immigration, on certain frauds perpetrated by aliens. The Administration has discovered that in nearly every State in the Union a large percentage of the inmates of asylums for orphans are children who have been sent to this country especially for the purpose of being placed in such institutions, where the care is better than that given in European institutions. The facts will be presented to Congress.

Tuberculosis in the Post Office Department.—An order has been issued by the Civil Service Commission debarring consumptives from government employment in positions which bring them in contact with the public. The order applies particularly to post offices, and states that hereafter all applicants for employment with the government must submit to a physical examination, if the presence of tuberculosis is suspected, and that if the disease is found the sufferer shall not receive an appointment.

The Hospital Ship of the Hull Fishing Fleet.—The hospital ship *Alpha,* which carried some of the victims of the Russian naval engagement in the North Sea back to Hull, is a steam trawler belonging to the Royal National Mission to Deep Sea Fishermen. *The Hospital* says that she is adequately fitted in every way, and carries an *x*-ray equipment. The swing cots, which are particularly comfortable, are amidships. The *Alpha,* like every other hospital ship belonging to the Mission to Deep Sea Fishermen, carries a fully qualified medical man, and every Mission skipper holds a certificate for "first aid." The ship's nurse is the surgeon's mate, who is also responsible for the care of the dispensary. Besides being a floating hospital, the *Alpha* trawls, like any other steam trawler.

Medal for Best Hospital Plans.—Dr. A. J. Ochsner and Meyer J. Sturm, of Chicago, were awarded a gold medal for hospital plans exhibited at the Louisiana Purchase Exposition. Plans of a city hospital, a country hospital, a hospital for towns, and a hospital for the treatment of contagious diseases were exhibited, showing a radical departure from any existing hospital structures now in use.

Illinois State Board of Health Wins Medal.—A gold medal has been awarded this Board for its ex-

cellent exhibit in the section of hygiene at the Louisiana Purchase Exposition.

Trained Nurse for Bridge Crowds.—A waiting room with a trained nurse in attendance is to be installed at the Manhattan end of the Brooklyn bridge for the purpose of caring for cases of fainting and minor injuries.

Japanese Medical Commission.—A Japanese imperial medical commission which has been studying the Health Departments of the principal cities of this country and Europe arrived in this city last week. The members of the commission are Professors Tanba, of the Department of Pharmacy, Takamine, of the Department of Chemistry, and Mortora, of the Department of Psychology, and Dr. Sato, Chief Surgeon, all of the Imperial University at Tokio. The commission visited the Health Department and a number of the hospitals here.

The New York County Medical Association will hold its regular monthly meeting at the Academy of Medicine on November 21. A paper on "The Dangers of the *x*-Ray" will be read by Dr. Milton Franklin and discussed by Drs. Allen, Beck, Coley, and Morton. The second paper will be on "Medical and Surgical Features of the Russo-Japanese War," by Dr. Louis L. Seaman. This will be discussed by Surgeon-General Wyman, of the P.H. and M.H. Service; Captain Purokowski, of the German Army; Major Powell, Surgeon U.S.A., and others.

Smoker of the Eastern Medical Society.—The annual smoker and social reunion of this society was held at Clinton Hall on the evening of November 5, and was unusually successful, being marked by a large and enthusiastic attendance. Dr. E. K. Browd was the chairman of the house committee in charge of the entertainment.

Race Suicide in France.—The vital statistics of France show a continuance of the decrease in the birth rate as compared with other nations, for while the excess of births over deaths in 1901-1902 was 21 per 10,000 inhabitants, the ratio for the same period in Germany was 153 and in Great Britain 119. The official figures just published of the population of France in 1903 are as follows: Births, 826,712; deaths, 753,606; excess of births, 73,106; excess in 1902, 83,944. The population of France in 1902 was 38,961,945, and in 1903 was 39,119,095, but in 1903 there were 18,666 fewer births than in 1902. The number of deaths was fewer by 7,828 than in 1902. It is pointed out in the report that the increase of population was not due to any increase in the general birth rate, but solely to the steadily declining death rate.

Obituary Notes.—Dr. Samuel Woodhouse died at Philadelphia on October 24 at the age of 83 years. He was graduated from the Medical Department of the University of Pennsylvania in 1847. He was surgeon at Fort Delaware in 1854, and at one time resident physician in the Philadelphia Hospital and the Eastern Penitentiary. In the capacity of surgeon he accompanied the expedition to establish the boundary between the Creek and Cherokee Indians, and he was a member of the Sitgreaves-Zuni expeditions to New Mexico and Central America.

Dr. Mordecai Price died at Philadelphia on October 29 at the age of 61 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1866.

Dr. David G. Hetzell died at Philadelphia on October 26 at the age of 68 years. He was graduated from Jefferson Medical College in the class of 1858. At the outbreak of the Civil War he became assistant surgeon to the Thirty-fourth New Jersey Volunteer Regiment. Later he served with the Twenty-third New Jersey regiment and he remained in the service to the end of the war.

Dr. Guilford H. Gunter died at Camden, N. J., on November 5 at the age of forty-six years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1881.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent)

MEDICAL SOCIETY—MIDWIVES' BOARD—SMALLPOX RESEARCH—WATERLOO HOSPITAL—CREWKERNE HOSPITAL—HOSPITAL SATURDAY—PROPOSED PENNY FUND—OBITUARY NOTES.

London, October 21, 1904.

The session of the Medical Society of London opened with its annual meeting on the 10th, when, after formal business, the incoming president, Mr. John Langton, delivered his address. He referred to the deaths of Fellows during the year, particularly Sir W. Mitchell Banks and Dr. Gilbart Smith, both of whom had taken prominent positions in the work of the society. He then passed on to consider some of the problems that have recently attracted the close attention of the profession. As to tuberculosis, he remarked that Great Britain now had the lowest death-rate. He compared aseptic and antiseptic methods in surgery, emphasizing the former. With regard to cancer, he noticed the importance of Dr. Bashford's discovery of the conjugation of the young cells. He then dwelt at length on the radical cure of hernia—an operation dating from Celsus. He had operated on 2,319 patients, only nineteen of whom had died, less than 1 per cent. Hospital statistics were likely to be fallacious, as two to four years should elapse before the true result could be stated. Out of 246 private cases he had ascertained the results in 214. Three had been fatal—one from acute sepsis, two from venous embolism. Only twenty-six had relapsed. The chief question at present was the age at which to operate. It was certainly best to do so in early life—some said as early as possible. But the time would vary with circumstances. Hernia in children might disappear from time to time. Continuous pressure never cured.

After the address, Mr. Marmaduke Shield read an account of a case of gigantic renal calculus, illustrated with remarks on cases where renal stones form obvious tumors. In Mr. Shield's case the calculus, which entered up into the dome of the diaphragm, was ten inches in circumference, and in the dry state weighs sixteen and one-half ounces. The patient had had attacks of hæmaturia from 1890, but had not laid up until 1903, when he was in hospital for fourteen days. Last January he had an attack with pain, which laid him up for three weeks. On February 10 he was obliged to give up work. On the 19th operation was performed, the diagnosis being doubtful and inclining to malignant tumor. On dividing the abdominal wall, an abscess which contained two small stones was opened. The gigantic stone was then felt and with difficulty removed, as was the "shell of the kidney." The patient recovered, and is now at his work (omnibus conductor). Mr. Shield directed attention to the fact that a large renal calculus or a number of small ones may form an abdominal tumor, the nature of which may easily be misunderstood. In the museum of St. Bartholomew's hospital there is an enormous calculus which weighs over two pounds. A tumor was detected during life; the patient died suddenly, and at the post-mortem this and other calculi were found. The value of *x*-rays, Mr. Shield said, was in these cases limited, an opinion with which subsequent speakers, including the president, coincided. Mr. Mayo Robson said the origin of such tumors could be made out by distending the colon with air. A Higginson's syringe would serve the purpose. With this he had only once failed to detect the origin, and that was in a case of suprarenal tumor. I think the slight amount of pain in some of these cases very remarkable, and no doubt to some extent it depends on the smoothness of the calculus, as small, jagged stones often give rise to intense suffering. In fact, so far as my limited experience goes, renal calculus is always very painful. Yet, in the cases under consideration the encroaching calculus leaves but a mere shell of renal tissue by the time surgical aid is sought.

The Central Midwives' Board has at last yielded to the ridicule and indignation provoked by its absurd attitude towards the Dublin schools of midwifery. The board has intimated to the Rotunda its intention to ask the Privy

Council to modify the rules so as to allow the Rotunda certificates to be accepted. It was time, indeed, to make the concession, unless the egregious Board desired to perish by its own ineptitude. I have previously reported to you some of its absurdities, and perhaps no Board has ever equalled them. The favorite plan of governments to refer troublesome questions to commissions, or to settle them for a time by committing them to Boards, has often resulted in mere postponement, or in prolonging the state of unsettlement, as in the case of the Medical Council, which has never given satisfaction, and in this newly authorized Midwives' Board.

This last threatens to prove a tolerable representative of the "ignorant gumps" it was proposed to get rid of. At its meeting on the 29th ult., there was one medical man, two ladies and a chairman. A complaint was made against one of its registered midwives, who had been previously written to by a doctor, and had replied, "It is much like your *impotence* to write to me, so please mind your own business." The Board resolved it could not move until a local authority requested. Then a letter from the Obstetrical Society was read, announcing that its certificate had been revoked in the case of a midwife, whereupon the ladies of the Board resolved to demand evidence as to the charges. After this the ladies resolved to give their advice as to the suitability of some hospital wards. Probably the ladies, if asked, would be willing to superintend surveying or building hospitals. But they refused to agree to the proposal of the medical member to have the statement of accounts sent out a few days before the meeting, so that members might have time to consider them. The chairman joined in with the ladies and declared the doctor's suggestion unnecessary, so until a further proposal is made and carried, members of the Board must be content with a hurried glance at the accounts when produced at a meeting.

On Saturday the Asylums Board discussed a report of their Hospitals Committee stating that the Local Government Board had sent a letter mentioning that thirteen London Boards of Guardians had protested against one of the hospitals being used for experiments on animals in connection with the causation of smallpox. The Local Government Board asked for particulars. The committee merely pointed out that it is most desirable to find out the cause of the disease, and reduce the great expense incurred in its treatment, and that the hospitals of the Asylums Board presented the only opportunity of investigation in London. An amendment disapproving the committee's report was moved, but it was lost. The report of the committee was then agreed to.

The Duchess of Albany presided on Tuesday at a meeting of the Ladies' Commission of the Royal Waterloo Hospital for Children and Women. The rules of the association were adopted. An executive committee was formed and a room in Mayfair has been offered as an office free of rent. It is now determined to form a Children's Guild on the same lines. The duchess was elected president of the association and the Princess Alexander of Teck of the Guild. With these two organizations formed to help it the hospital ought to prosper.

Crewkerne has built a hospital as a memorial to Queen Victoria, and, what is more, has paid for it. It was opened free of debt on Tuesday, the cost being £53,000. The opening ceremony was perfromed by Sir F. Treves, who at the subsequent luncheon said it was admirably fitted, replete with modern conveniences, excellently designed, and perfect in all its details. He congratulated the architect and builder and wished the hospital success.

Hospital Saturday was kept in London and the suburbs for the thirty-first year, on Saturday last, but the returns from the district committees cannot be completed for about a fortnight.

Perhaps we shall escape the infliction of a penny hospital fund, which, I mentioned a month ago, had been proposed by a journal. The scheme was to sell booklets of hospital stamps and give 75 per cent. to certain hospitals. Already several of the hospitals have protested against the plan and refuse to be in any way associated with it.

One of the oldest practitioners in Scotland, Dr. James Wallace, J.P., was found dead in his bed on the 10th inst. He was in his usual health on the night before. He was in his 80th year. He was a Glasgow graduate, M.A. and M.D., and formerly an examiner in that university. He had also been for more than thirty years surgeon to the Greenwich Infirmary, and was medical officer of health for that town at the time of his death. At his doctor's jubilee in 1902 he was entertained at a banquet and presented with his portrait and an illuminated address.

The death is announced of Mr. Henry Campion, M.R.C.S., the leading dental surgeon of Manchester, who retired a few years since, after a career in which he gained the respect of all who knew him. He played an important part in the dental reform movement. In 1882 he was elected president of the British Dental Association, in succession to Sir J. Tomes. He also served the presidency of the Manchester Odontological Association, and was for many years surgeon to the Victoria Dental Hospital, and afterwards consultant to it.

MUSIC AS A THERAPEUTIC AGENT.

To the Editor of The Medical Record.

Sir: Dr. Kennedy's paper on "Music as a Therapeutic Agent," in the Medical Record of October 29 last, is full of interest. Psychiatrists have long recognized the beneficent influence of music on the insane. It would be difficult, in my opinion, to go among the physicians in the State Hospitals of this country and find one of experience who did not agree with this statement. Personally, I had ample opportunity for observing it during a five years' service in an institution for the insane, and I have witnessed the same thing among the epileptics at Sonyea.

There are cases of epilepsy in which stimulation of the emotions, or the imagination, along certain lines (erotic, for instance), will induce epileptic attacks, and others in which the influence of musical harmony acting on an agitated and unbalanced nervous system, will restore it to a more nearly normal condition.

Last summer a musical service by a celebrated violinist was held at the Craig Colony in place of the regular service, which usually embraced a sermon few of the patients could understand in a way to keep them mentally alert and interested in what was going on. The result of the musical service was striking. Instead of eight to ten seizures during the hour, two only occurred, both being innocent in character; that is, neither was active nor demonstrative.

Dr. Merrins, in studying "The Malady of King Saul," which he concludes to have been epilepsy, says: "The Evil Spirit is said to have 'terrified' Saul. We have already seen that among the psychical aura is a sensation of fear, of terror, or a fixed idea that some calamity was impending. David's music is said to have made Saul breathe more freely" (Bibliotheca Sacra, October, 1904).

My chief purpose in writing this is to call attention to the possible value of carrying out some experiments along this line in institutions for the insane and epileptics. It would be an excellent thing if the Rockefeller Institute, for instance, could be induced to set aside a fund of $1,000 for this purpose; the experiments to be carried over several months, and to include cases carefully selected for the purpose.

W. P. Spratling, M.D.

Sonyea, N. Y., November 1, 1904.

Marmorek's Anti-Tuberculous Serum in the Treatment of Pulmonary Tuberculosis.—Arthur J. Richer believes that antitoxins exercise a toxic influence if given too late in the disease. This is notably the case in diphtheria. In the case of tuberculosis, we are dealing with a disease in which the types clearly differ. There are, for example, many cases in which there are localized or discreet lesions, these patients never showing any effect of toxine absorption. Again, there are other patients showing exacerbations during the course of chronic tuberculosis, in which the influence of the serum seems limited to the recent involvements. The writer then appends a number of observations of various types of the disease treated with Marmorek's serum. Although it is as yet very difficult to say whether Marmorek's anti-tuberculous serum possesses bactericidal powers, the writer feels positive as a result of clinical tests that it is truly an antitoxin, and that it does possess the power of inhibiting the growth of the tubercle bacillus, but as with all antitoxins, this power is ephemeral. The writer reports a case in which the physical signs had entirely disappeared after thirty inoculations, while what little expectoration still persisted was free from bacilli; yet two months after this hopeful report the patient now shows some bacilli in the sputum, and some indication of the return of the disease at the original spot. The writer thinks that now that we have fair evidence that we possess an antitoxic serum capable of conferring passive immunity, we have every reason to believe that it can be further made use of to protect human beings while under treatment with bacillary extracts of the tuberculin group in attempting to make the human organism under treatment produce its own antitoxin, as well as its bactericidal humors. The writer is now attempting that form of treatment.—*The Montreal Medical Journal.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, November 3, 1904.

Three Cases of the Association Neurosis, with Remarks on Its Genesis.—John E. Donley reports these cases. The first patient was a man who, previous to an attack of herpes zoster, had always been in good health. This attack occurred about nine months ago, and was accompanied by severe pain. Although the external appearances of the trouble disappeared in due time, the pain continued. About 5 o'clock every morning, before the patient was up, this pain began. It had no relation to muscular activity. Indeed, if the patient got up and moved about for a few minutes the pain would disappear. The patient was mentally depressed and discouraged about himself. For its suggestive effect, faradism was applied to the spine, and a bromide mixture was administered. The patient was assured that this treatment would result in relief. He was told not to get up till 6 o'clock the next morning. The pain was not so severe on this morning, and after continuing the treatment for ten days it completely disappeared. The other two patients were troubled with nausea and weakness, but were entirely relieved by suggestion. The writer states that association or habit neuroses constitute a large class of purely functional nervous affections, in which the disagreeable features result from an atypical or not normal association of elements, which in themselves are in no sense pathological.

New York Medical Journal, November 5, 1904.

Woman's Duty Toward the Health of the Nation.—S. A. Knopf considers that every American woman should familiarize herself with the status of the national health so that they may act intelligently. They should further their own health by proper dress and food and a simple life. They should nurse their own children and understand the proper cooking of food. They should put themselves on record as to their belief in the efficacy of vaccination for smallpox, antitoxin for diphtheria, and modern methods for stamping out tuberculosis. They should take a firm stand against the fallacies of the "anti-vivisectionists." They should carefully instruct their children against the evil effects of alcohol and decry the indiscriminate use of patent medicines. There is a call to-day for broader education, heroic example, self-sacrifice, much work, and a great deal of devotion.

A Clinical and Statistical Study of Convergent Strabismus.—W. Reber presents the following propositions: Esotropia is most likely to manifest itself before the end of the third year. The degree of deviation will average about 30° in a large number of cases. It is in no special way bound up with the degree of refractive error. The amblyopia of esotropia is presumably an amblyopia ex anopia, the present day evidence being against Sahweigger's theory of a congenital amblyopia. The degree of amblyopia increases with the length of time elapsing between the appearance and the time of treatment. Improvement may be expected in the amblyopic eye in fifty to sixty per cent. of cases by properly adjusted glasses. While a defectively developed fusion apparatus has much to do with the genesis of esotropia, the influence of hypermetropia and its allied states seems almost as important as in the days of Donders. The part played by astigmatism is no little one. A very high degree of hypermetropia does not necessarily exclude strabismus, as three cases in the series presented were of 11 D. and over. If taken before the fifth year there seems no reason why the strabismus should not be cured by non-operative methods in seventy per cent. of cases. This percentage will, in all probability, be increased to eighty per cent. in the next ten years. The results of non-operative treatment in children, if adhered to with any persitence, are infinitely better than any "scissors" statistics thus far offered.

Medical News, November 5, 1904.

Report of a Case of Splenomedullary Leukæmia Treated for Nine Months by the X-Ray.—William Fitch Cheney reports a case of this kind. The patient, a man of 27 years, had been treated by all of the ordinary and well-tried methods employed in this ailment. No treatment had ever done more than to temporarily mitigate the symptoms. The *x*-ray treatment was then begun and up to date 144 applications have been given (in a period of 9 months). The general condition has been so much improved that the writer declares that from a symptomatic standpoint the man is cured. But the other manifestations of the disease have not kept pace with the symptoms, although there has been improvement. The free fluid which had been noted in the abdomen has disappeared. The spleen has become gradually more freely movable in the abdomen and the tension has decreased so that the wall has become less resistant to palpation. The contour of the splenic tumor, however, has not materially changed. Blood examinations show a decided change for the better. No ill effect of the treatment has been observed except the dermatitis.

Endotracheal Medication.—J. J. Richardson believes that in intratracheal injections we have a valuable method of treating many of the inflammatory and infective diseases of the lower respiratory tract. The syringe used by the writer consists of a glass barrel inclosed in metal and having a spiral spring attached to the piston. The medicaments used should in general be antiseptic, stimulating, non-irritating, and soluble in the vehicle employed. Oily solutions are now used with excellent results. The diseases treated have been bronchitis, bronchial asthma, trachetitis, bronchiectasis, and pulmonary tuberculosis. The greatest field of usefulness of this method is in the treatment of bronchitis. The writer advocates for these cases the use of 5 per cent. camphomenthol with eucalyptus and thyme and sterilized olive oil, or a highly refined bland petroleum. A few injections will often entirely relieve the cough and expectoration. The injections should be given daily, and one or two drachms of the liquid may be injected at a time. This treatment neither disturbs digestion nor interferes in any way with other treatment which may be carried out in conjunction with it.

American Medicine, November 5, 1904.

The History of Pediatrics and Its Relation to Other Sciences and Arts.—A. Jacobi presents the following conclusions: Pedology is the science of the young. The physical, intellectual, and moral conditions of the young who are the future makers and owners of the world will decide whether the globe will be more Cossack or more Republican, more criminal or more righteous. The physician, mainly the pediatrist, should become responsible for their education, training, and capabilities. Heredity and the health of the pregnant mother are the physician's concern. The regulation of labor laws, factory legislation, and the prohibition of marriages of epileptics, syphilitics, and criminals are some of his preventive measures to secure a promising progeny. To him belongs the care of the production and distribution of foods. He has to guard the school period from sanitary and educational points of view, for heart and muscle and brain are of equal value. It is in infancy and childhood, before the dangerous period of puberty sets in, that the character is formed, altruism inculcated, or criminality fostered. The physician has great possibilities and responsibilities. It is not enough that he work at the bedside and in the hospital. In the future he is to control school boards, health departments, and legislatures. He is the legitimate adviser to the judge and the jury. The writer concludes by urging the physician to participate in politics and never to miss any of his public duties.

Taine's Ill-Health.—George M. Gould gives an interesting sketch of this brilliant student. His troubles began at the age of 21, and by means of excerpts from his letters and from his biographers' notes, a sketch of his life is given from that period till the age of 36. It is the history of unrelieved eyestrain. The patient suffered greatly with headache, insomnia, depression, limited power of working, and inability to use the eyes. With all this suffering, however, his letters often speak of being in "good health" during the very periods when he was temporarily suffering from migraine. The writer states that such an experience is a well-known clinical fact. He states that in the case of the reflexes of eyestrain the clinical histories are likely to vary astonishingly according to the organs that bear the brunt of the derouted nerve discharges. But even in the most aberrant types there are certain facts and phases common to all. The suffering, whatever its form, is directly consequent upon the use of the eyes. It increases in intensity with the lessening of the accommodative power. The only way of stopping the suffering is by nonuse of the eyes. Depression is always present. As the disease is functional and not organic, the essential health and vitality are not, at least for a long time, if ever, irremediably affected. A late photograph of Taine (he lived till 1893, dying at 64) shows that toward the end of life there was paretic ptosis or drooping of the lids. The right eye is plainly strabismic, or turned in. The writer concludes by calling attention to the case with which the entire list of evils suffered by Taine can be prevented in modern patients.

Röntgen Ray in the Treatment of Sarcoma.—Joseph F. Smith declares that in his hands the Röntgen ray has been a disappointment in the treatment of sarcoma. In no case has there been the slightest evidence of benefit from the treatment of large primary or secondary tumors when covered by skin or other protecting tissues. The writer believes that the only hope of benefit from the employment of the Röntgen ray in these cases and the treatment which would seem to offer the patient the greatest probability of cure is through surgical removal of the entire tumor, or as much of it as possible, and the application of heroic doses

of the Röntgen ray to the open field, carrying the treatment to the extent of producing necrosis of the healthy tissue immediately about the site of operation. In the treatment of carcinomas, the writer's best results with this treatment have been obtained in the case of epitheliomas or other superficial carcinomas.

Journal of the American Medical Association, November 5, 1904.

Some of the Therapeutic Uses of Hydrastis.—W. B. Stewart gives his experience with this remedy, which he has found especially useful in many forms of chronic catarrh of the intestinal tract, especially in alcoholic patients. For this purpose he prefers the fluid extract. It is superior for this purpose to the hydrastic. For local use he prefers the glycerite, which is especially serviceable in sub-acute and chronic conditions of the genito-urinary tract. The hydrastin in muriate is an excellent remedy for menorrhagia and should be given in doses of from one-fourth to a grain. It is slow in action, but the latter is more prolonged than is that of ergot. It may produce abortion in pregnant women. It is useful also in epistaxis, hæmoptysis, hæmatemesis, and hæmaturia.

How to Produce Milk for Infant Feeding.—E. F. Brush details his dairy experience and declares that dairymen should be held responsible for the stomach and intestinal condition of otherwise healthy infants fed on milk that they furnish, providing that nothing is added, except sterilized water, cane sugar, or cream that comes from the cows under their control. Certainly the milk must be carefully guarded, kept cold, below 50° F., and away from contaminating influences, or the addition of milk sugar, lime water, pepsin, pancreates, or any other articles except as above specified. He maintains that the surest test that milk is good food for the baby is the baby itself. The percentages of fat, the proportions of proteids, and all the other chemical data amount to nothing, if the baby is thriving the milk is good.

The Initial Contamination of Milk.—R. C. Newton refers to certain advances which have been made in the conduct of modern dairies. He believes, however, that it is impossible to produce actually sterile milk as judged by bacteriological tests. The covered pail should come into general use. The requirements which will produce a milk coming up to the "certified" standard are not unsurmountable even for the small farmer with only a few cows, provided certain essential rules of cleanliness are followed and the proper utensils employed. The covering of the pail with a sterile cheese-cloth diaphragm is undoubtedly one of the safest as well as one of the simplest measures of safety. Elaborate statistical tables are introduced to support the author's contentions.

The Use of Nitroglycerin in the Treatment of Erysipelas.—On the basis of four cures this remedy is highly extolled by J. W. Wherry. The customary dose of 1-100 grain is given every three or four hours. An ointment of ichthyol and zinc oxide was used in each case, but the author ascribes to it only a soothing effect on the skin, and in one instance it did not even produce this effect, for the patient would rub it off as fast as it was put on. All these cases presented several features in common as the result of this internal treatment, viz., a reduction of temperature, moist skin, good appetite, steady pulse after the first day, absence of prostration, general feeling of comfort, and a fairly rapid disappearance of the inflammatory process.

The Lancet, October 29, 1904.

On Streptococcal Infection and the Use of Antistreptococcic Serum.—S. Anderson reports two successful cases, and says that to achieve the best results with the remedy the following factors seem necessary: (1) That where the infection is "single" and a polyvalent serum is obtainable possessing the "immune body," it should be applied as soon as the illness is recognized, the object being to inject before much toxin has formed. (2) That the serum should be as fresh as possible. (3) In those cases in which the serum is doing good, there is no danger in administering an excess, and also from the above arises a second corollary, viz., that in those cases where there is no apparent benefit there is no evidence to show that it does harm. (4) That since the serum acts mainly by increasing phagocytosis and since in certain cases very little antidote is formed, the administration of the serum should be continued for some time after apparent recovery until its action is quite complete.

Purpura Convalescentium Following Measles of Mild Variety.—J. Fortune records the case of a girl of five years who had apparently an ordinary measles, but on the fifth day she had epistaxis, and the entire skin was mottled with a petechial rash, and the urine contained some blood. There was no fever, and all the organs seemed normal except the spleen, which was somewhat enlarged. There had been no vomiting sickness, convulsions, or joint swelling. Pulse was 112, soft, and full. There was an exhavasation in the right labium. Under tannic acid insufflation the nose bleed ceased. Internally ergot and chloride of calcium were given, and under these remedies all the symptoms gradually abated and recovery followed. The author believes that the petechial rash was a sequel of the action of the measles toxin.

British Medical Journal, October 29, 1904.

Spasmodic Neuralgia Treated with Bromide.—J. H. Potter describes the case of a woman, aged 81 years, who had suffered nearly all her life from attacks of neuralgia of the fifth nerve, and for the last three months from spasmodic paroxysmal attacks. The age of the patient was against the excision of Meckel's ganglion. Of all the drugs employed, injections of morphine were the only thing that gave even partial relief. The writer decided to try the effect of large doses of bromide and gave a teaspoonful of powdered potassium bromide in milk, with immediate relief. The dose was repeated at night. There has been no pain since the second dose. The patient now sleeps and eats well and requires no morphine at night. The patient is convinced that her relief is the result of the medicine, as on no other occasion has the pain ceased so suddenly.

Experiments on the Dissemination of Tuberculosis in the Female Genitals.—Baumgarten reports on some interesting work done in co-operation with Basso to study the course of progression of genital tuberculosis in the female. Over fifty rabbits were used and the results obtained were consistent in all cases. The lower and upper portions of the vagina, the horns of the uterus, and the pertioneal cavity were infected either with emulsion made from perlsucht nodules or with actual bits of the tissue itself. The peritoneal infections never invaded the tubes or any other portion of the genital tract, and though infection starting from the uterine coruna readily traveled downward it never progressed in the opposite direction toward the distal end of the tubes. Infection of the vagina never passed upward, but only downward, and only the urethra was invaded of the urinary tract. The author, therefore, concludes that, as he has already shown for the male, so in the female tuberculosis of the urinary and genital systems is not reciprocal and that in each case it follows the direction of the normal local currents. In the genital tract this is from the ovary toward the vagina, and in the urinary tract it is in the direction of the urinary flow. Common ground for the two types of infection is, in the male the prostate, and in the female the urethra and lower vagina.

Mechanical Compression of the Thorax in Dyspnœa.—Boghean says that the treatment of dyspnœa by the various respiratory drugs and other measures at our command is still very unsatisfactory. The question of whether it is the accumulation of carbon-dioxide or the lack of oxygen that is the more important factor in the production of dyspnœa has been answered by the researches of numerous observers, who state that both of these elements are concerned in the production of the condition, but that the body is much more tolerant of deficiency of oxygen than of excess of carbon-dioxide. Numerous forms of apparatus have been devised for the purpose of mechanically assisting the expulsion of the air from the lungs by compression of the thorax, but they have been unsuitable for general application on account of the lack of a suitable motive power. The fatiguing nature of the work renders it impracticable to have either the patient himself or an attendant furnish the energy required, and the author describes and illustrates a somewhat complicated chair provided with pads, to be applied over the front of the patient's chest, and operated by a small electric motor. The machine once set in motion compresses the thorax at each expiration to a greater degree than the patient's unaided efforts could, and by increasing the carbon-dioxide output promptly relieves the subjective sense of dyspnœa.

Münchener medizinische Wochenschrift, October 18, 1904.

Sequestra of the Lung.—Büdinger describes the operative removal of a pulmonary sequestrum following abscess. The patient was a middle-aged man, who suddenly developed a septic process in the right lung, which, after the lapse of some weeks, gave signs pointing definitely to abscess. The third rib was resected and the greatly thickened pleura incised, revealing a large cavity filled with pus. In this cavity a detached mass of lung tissue was observed, and on drawing it out of the incision it readily separated from its attachments. The mass was the size of the first and had evidently possessed a pedicle containing a good-sized bronchus, for it was well aerated. The cavity was drained and the patient made a good recovery. A portion of an ear of wheat was found in the interior of the mass, and had evidently served as the original source of infection. The author gives a résumé of what is known concerning this very rare condition, and says that it may be caused by a dis-

secting pneumonia, by abscess of the lung, and by combinations of abscess of a superficial part of the lung with empyema.

The Simulation of Mental Disease.—Schott says that the simulation of insanity in perfectly sane individuals is very rare, and that it is usually found associated with mental degeneration of greater or less degree, forming one symptom of the morbid state. In other words, the fact that an individual confesses to having simulated insanity does not prove him to be mentally sound, for simulation and mental disorders frequently are associated. Great care and prolonged study is frequently necessary in these cases, and a diagnosis of malingering is to be made only when there is positive proof of the individual's sanity. Violent measures are not justified in attempting to "unmask" such persons, though a device that is often successful is to mention in the subject's hearing that some specific symptom—bed-wetting, for example—is lacking to complete the picture, when the malingerer will usually promptly supply it. Even then, however, caution is needed to exclude hysteria. In all cases of this sort prolonged observation in an asylum by specialists is essential.

The Pathogenesis of Postanæsthetic Paralysis.—Glitsch discusses this question in the light of a case of his own, and of some experiments on the cadaver he was induced to make in consequence of his experience. According to the commonly accepted views, the paralysis is produced by pressure on the bracchial plexus, either through compression between the first rib and the clavicle, owing to the approximation of these bones, resulting when the arm is raised above the horizontal line, or through direct pressure of the head of the humerus, owing to the greater prominence of the latter caused by elevation of the arm. In the author's case there was great relaxation of the capsule of the shoulder joint, probably due to an old inflammatory process, possibly tubercular, on both sides, and by experiment with a cadaver, after opening the joint so as to permit subluxation of the bone, he found that in certain positions of the arm direct pressure was caused by the head of the humerus on some strands of the plexus. The position giving rise to this pressure was that of hyperelevation of the arm, combined with inward rotation. The author, therefore, advises that the greatest care be taken to avoid this position, and that the arms should frequently be moved during the course of long operations. If medico-legal complications arise in such a case, it is necessary to make careful search for some predisposing condition, such as relaxation of the capsule, joint disease, etc., as this may furnish the conditions suitable for the causation of the pressure paralysis.

Deutsche medizinische Wochenschrift, October 20, 1904.

The Significance of the Venous Valves in Relation to Varicose Veins.—Ledderhose believes that the conventional views as to the functions of the valves in the veins are inexact, and that these play a less important part in the mechanism of the circulation than is usually taught. He discusses in detail various theoretical considerations, discrediting the ideas that the hydrostatic column of the blood in the veins of the lower extremities is supported by the venous valves; that these are a feature in assisting the muscular action to accelerate the circulation and that the valves prevent regurgitation of the blood stream in sudden changes of position of the limbs. The importance of the valves is further belittled by the fact that they decrease rapidly in number with increasing years, at the age of twenty-five 17 per cent. have disappeared, and at the age of seventy 81 per cent. have been lost. The author's theory is that in most cases the valves play no part in the adjustment of the circulation, but that this is, as a rule, effected by retrograde stasis and variations in speed. The author applies these views to the subject of varicose veins and their cure by Trendelenburg's operation of ligating the saphenous vein. The aspirating effect of movement at the large joints on the vessels causes blood of the femoral vein to be drained out more rapidly in the act of walking, and if the saphenous vein has been ligated the varicosities can more easily discharge their contents into the deeper vessels without receiving any additions from the long saphenous blood column.

The Treatment of Tumors, Especially Ovarian Cysts Complicating Pregnancy and Labor.—Dührssen advocates vaginal operation as warmly during pregnancy as he does in the absence of this complication, and describes a number of cases in which tumors were easily removed under these conditions. The attempt to replace incarcerated ovarian or parovarian cysts in pregnancy or during labor by forcible manipulations with or without anæsthesia is unsafe and should never be resorted to, owing to the danger of injury to the pedicle with consequent internal hemorrhage. In such cases the proper treatment is vaginal ovariotomy, to be succeeded by laparotomy, which, if the proper preparations have been made, does not increase the danger to the patient. During labor abdominal removal of the tumor is to be preferred only in case the genital tract or the tumor contents have become infected. During pregnancy tumors which can be pressed down into the anterior or posterior vaginal vault are to be approached through the vagina. Tumors which are situated too high up to be made accessible in this way should be left untouched during pregnancy, provided they do not increase in size and that the general condition remains good. After involution has taken place these growths may also be removed by vaginal operation. Myomata which block the paturient canal and are not drawn up by the uterine contractions may be exercised either by anterior or posterior colpotomy, together with vaginal cæsarean section. The uterus may then be emptied and extirpated, or the different tumors may be enucleated and the necessary incisions closed by suture.

Annals of Surgery, September, 1904.

Adenoma of the Mucous Glands of the Lips as a Cause of Macroeheilia.—Daniel Eisendrath reports such a case which is interesting not only from a diagnostic, but from a prognostic, standpoint, owing to the fact that some of the cases diagnosed as epithelioma of the lip may prove on microscopical examination to be carcinomata of the glandular type arising from these glands. So far as he could determine this is but the second case of adenoma of the mucous glands that has ever been reported.
